IRON

THE therapeutic value of iron is directly proportional to the ease with which ferrous ions are liberated. Recent experiments have shown the ferrous salts to be the most effective in the treatment of anemias because they are more rapidly assimilated, require smaller doses and are more economical than other forms of iron now in use. An effective form of ferrous iron is available in Hematinic Plastules . . . Actual tests reveal that the absorption of ferrous sulphate in Hematinic Plastules is four to five times greater than that of ferric ammonium citrate, 15 times greater than that of reduced iron, and is more readily adaptable to metabolism in the human body. Three Hematinic Plastules Plain provide the average patient with an adequate daily dose of iron to show a marked increase in hemoglobin. . . . Hematinic Plastules provide ferrous sulphate and vitamins B and G in an edible oil in the form of a semi-fluid mass, enclosed in soluble gelatin capsules which quickly dissolve in the stomach. . . . Hematinic Plastules are available in two types—Plain and with Liver Extract.

In Infant Feeding

THE DOCTOR IS CONCERNED ABOUT THE COMPOSITION OF A MILK-MODIFIER!

WHEN you prescribe Karo as the milk-modifier you are providing well-tolerated, readily digested maltose-dextrins-dextrose. The dextrins are practically non-fermentable; the maltose rapidly transformed to dextrose requiring no digestion; the sucrose added for flavor is digested to monosaccharides. Karo is prepared chemically and bacteriologically safe—non-allergic, practically free from protein, fat and ash.

★ **Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.**

VITAMIN REQUIREMENTS OF MAN

III. VITAMIN A

• The importance and multiple functions of vitamin A in human nutrition are widely dealt with in clinical literature. Xerophthalmia resulting from severe vitamin A deficiency is rare in this country, yet the etiology of many pathogenic conditions, namely, night-blindness, urinary calculi, lesions of the nervous system, impairment of epithelial tissue and subnormal growth, has been linked with chronic avitaminosis A (1).

Minimum human requirements for vitamin A are influenced by such variables as size of the individual and efficiency of absorption. The minimum daily requirement of infants has been estimated at 1500 International units, based upon the vitamin A content of milk. The need for the vitamin is not supplied by 1200 International units, while 2000 International units appear to be sufficient (2).

Although the minimum requirement of the adult has been estimated to be as low as 500 International units, the optimum level for both older children and adults is probably between 3000 and 5000 International units per day (3). The League of Nations Technical Commission recommends over 5000 International units of vitamin A for the pregnant and for the lactating woman (4).

Since the human requirement is evidently high, it is fortunate that vitamin A and carotene (pro-vitamin A) are more or less widely distributed in natural foods. Outstanding sources are some of the highly pigmented fruits and vegetables—especially the yellow varieties—and also dairy and marine products (5).

These protective foods, preserved by modern commercial canning, are readily available in all parts of the country throughout the year. It has been repeatedly demonstrated that commercially canned foods retain their vitamin A potency to a high degree (6). The vitamin A potencies of certain commercially canned products have been recently reported in International units (7). From these reports it is apparent that commercially canned foods can be relied upon to supply quantities of vitamin A entirely consistent with the vitamin A of the raw product.

A Vacation Hazard

● The summer traveler or camper frequently accepts chances of infection by *Endamoeba histolytica*. Unguarded water supplies, food prepared by unknown hands, the unavoidable presence of the housefly—all contribute to the possibility of ingestion of the cysts of this organism.

Throughout the year the physician has many occasions to consider amebiasis in the differential diagnosis, inasmuch as 5 percent to 10 percent of the population of the United States is infected. The symptoms of amebic infestation are protean and suggestive of a variety of diseases of different etiologies.

Carbarsone, Lilly (p-carbamino phenyl-arsonic acid), is effective in treatment, is of low toxicity, and is usually successful without supplementary medication. It may be given orally in capsules or tablets, or it may be administered by retention enema. Supplied in 0.25-Gm. pulvules; in 0.05-Gm. and 0.25-Gm. tablets; in boxes of six 2-Gm. vials; and in one-ounce bottles.

Photomicrograph showing internal hemorrhoids due to pressure from inspissated stools.

Hemorrhoids . . .

Prophylactic and Corrective Use of

MUCILOSE
(STEARNS)

Pressure from the hard fecal masses of constipation is one of the most important causes of hemorrhoids. Hence the rationale of Mucilose therapy which is directed at their etiology—as follows:

MUCILOSE + Stools =
Soft, Pliable, Fecal Masses

In this way, Mucilose, by relieving pressure, helps prevent venous congestion and thrombotic hemorrhoids.

Mucilose may be used postoperatively to prevent recurrence, as well as prophylactically—particularly valuable as preventive treatment during pregnancy.

For a Test! The coupon will bring you a supply of the New Granular Mucilose with our compliments.

Mucilose—a hemicellulose (vegetable gum) prepared by a special process from the Plantago loeflingii—is now available in two palatable forms, **MUCILOSE GRANULES** and **MUCILOSE PLAIN.**

CASE III
ACETANILID SERIES
A series of case types where the dominant symptom is pain of nerve origin.

TABES DORSALIS

CHIEF COMPLAINT: Sharp, stabbing pain, more common in legs or arms, but may dart to other areas.

HISTORY: Lightning pains, sometimes resembling rheumatic pains, not increased by motion; numbness of feet, tingling, etc.

PHYSICAL: Pin-prick test shows delay of perception; analgesic zone around upper thorax; knee-jerk absent, etc.

SYMPTOMS: Irregular pains in legs diminish on pressure; muscle power and general nutrition good; bladder emptied with difficulty; sexual desire and power decreased; Romberg sign present.

DIAGNOSIS: Early ataxic stage of tabes dorsalis.

TREATMENT: (Symptomatic) Acetanilid, 5 grains repeated.

Williams holds that acetanilid will alleviate the pains of locomotor ataxy when nothing else will. (Minor Maladies).

Bromo-Seltzer provides 3 to 3.5 grains of Acetanilid, plus its synergists—Caffeine and Bromides—in each teaspoonful dose. Caffeine gently invigorates the mental processes. Bromides promote relaxation of overwrought nerves. Citrates improve digestion, tend to replenish alkaline reserve and give to Bromo-Seltzer its effervescent palatability.

Bromo-Seltzer relieves pain effectively and economically.
Requests for sample and literature receive prompt consideration.

A NEW USE
for
AN OLD PRODUCT

More than half a century ago there was made available a product destined to become a valuable part of the physician's armamentarium.

It was evaporated milk, originated by Pet Milk Company. Since then extensive clinical experiments by noted investigators in various branches of medicine have firmly established its usefulness to the medical profession.

One of the latest uses found for it is in the dietary employed in the treatment of intestinal disorders.

It is useful to the gastroenterologist because—

Concentrated to double richness, it supplies twice the nourishment of ordinary milk—is a better balanced food than the usual milk and cream mixture.

Sterilized in sealed containers, it can never introduce bacteria to cause infection of healing areas.

Forming small, soft curds, it is readily digestible—helps to avoid trauma of the tissues.

Add to these qualities, whey proteins adapted to the person sensitive to milk — extra vitamin D created by irradiation to facilitate utilization of calcium and phosphorus—lower cost generally than ordinary milk.

Result—a combination of qualities unequaled in milk in any other form, and especially useful to the gastroenterologist.

Samples and literature will be sent gladly on request.

CREAM OF WHEAT

NOTE THESE Therapeutic Indications, DOCTOR

★

In the pylorospasm and pyloric stenosis of infants

●

In peptic ulcer, gastric as well as duodenal

●

In gastro-intestinal upsets when mechanical blandness is required

●

In spastic colitis

●

In the various forms of ulcerative colitis

★

Of course Cream of Wheat is not a medication, Doctor. It is a splendid cereal, carefully prepared from the country's best hard wheat crops. But because it is so rich in fuel energy value, and because it is so thoroughly bland, mechanically as well as chemically, it finds wide application in many cases when a properly selected diet is essential for successful therapy. Cream of Wheat is easily digested, and rapidly releases its contained fuel value. It deserves your confidence and preference.

Send for a copy of the interesting brochure, "The Role of Carbohydrate Digestion and Metabolism in the Body Economy"; a postcard will bring it.

CO-ORDINATION

When the success of a plan depends upon its perfect execution there must be strict co-ordination between the individuals involved. No program of treatment can relieve the incidence of constipation unless the patient is willing to co-ordinate his efforts with those of the physician. That is why so many doctors prescribe Petrolagar for their patients. Its pleasant taste and gentle consistent action are acceptable to the patient as well as to the physician . . . . Five types of Petrolagar provide a choice of medication to suit the individual case . . . . Samples on request. Petrolagar Laboratories, Inc. • Chicago, Ill.

Petrolagar is a mechanical emulsion of pure liquid petrolatum (65% by volume) and agar-agar. Accepted by the Council on Pharmacy and Chemistry of the American Medical Association for the treatment of constipation.

IN FEEDING REGULATION

It's the Infant's Response

PROPERTIES OF KARO

Uniform composition
Well tolerated
Readily digested
Non-fermentable
Chemically superior
Bacteriologically safe
Non-allergic
Economical

•

COMPOSITION OF KARO
(Dry Basis)

Dextrin	50%
Maltose	23.2%
Dextrose	16%
Sucrose	6%
Invert sugar	4%
Minerals	0.8%

•

KARO EQUIVALENTS

1 oz. vol.	40 grams 120 cals.
1 oz. wt.	28 grams 90 cals.
1 teaspoon	15 cals.
1 tablespoon	60 cals.

The final test of the adequacy of a feeding is the response on the part of the infant. It is frequently necessary to give a milk mixture of a considerably higher caloric value than anticipated.

The giving of food of too low a caloric value to meet the infant's needs is usually the chief cause of failure in infant feeding. The energy requirements may be met by Karo added to the type of formula indicated.

For further information, write
CORN PRODUCTS SALES COMPANY
Dept. D N 1, 17 Battery Place, New York, N. Y.

★ Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.

(INDEX NUMBER)

CANNED FOODS IN THE CONTROL OF SUBACUTE DEFICIENCIES OF THE ANTI-PELLAGRIC FACTOR

As a result of his classical researches, Goldberger first proposed the name "Pellagra-Preventive Factor" for that component of the vitamin B complex which he found effective in the prevention of human pellagra. Subsequently, the terms vitamin "G" and sometimes vitamin "B_2" were used to designate this effective factor. However, until biochemical research has conclusively established its identity, it is now apparent that we had best return to Goldberger's original designation for that entity which protects the human against pellagra.

In contrast to the other vitamin deficiencies, cases of severe deprivation of the anti-pellagric factor are not uncommon in certain regions of the United States. It is also known that if the intake of food be drastically restricted for some reason—alcoholism, for example—pellagra may be encountered in localities in which the disease is not endemic (1). For these reasons, it is not unreasonable to suspect that subacute or latent deficiencies of the P-P factor may also be existent in this country.

In the absence of typical dermatitis, available means for the diagnosis of deficiencies of the anti-pellagric factor are not entirely satisfactory. The practitioner must rely upon a variable group of less specific symptoms such as glossitis, diarrhea, digestive disturbances, and nervous and mental disorders. However, consideration of these symptoms along with an evaluation of the diet upon which the subject had been maintained, may permit the conclusion that suboptimal intake of the P-P factor should be suspected.

The treatment of severe or perhaps even the mild manifestations of this dietary deficiency may require intensive therapy with food products or preparations known to be rich in the pellagra preventing factor. However, prevention of pellagra and maintenance of the cure appear to be largely matters of dietary regulation. In this connection, commercially canned foods deserve particular mention.

Goldberger and his associates directed considerable attention to evaluation of the pellagra-preventive powers of common foods. The values of foods, many of them canned foods, in the prevention of pellagra have been determined (2) by investigations in which human subjects were used.

In view of these facts, it is apparent that certain commercially canned foods will prove reliable, convenient and economical in the formulation of diets calculated to protect against mild or severe deficiencies of the P-P factor.

Dietary Principles in the Treatment of Gastro-intestinal Diseases*

By

ALBERT F. R. ANDRESEN, M.D., F.A.C.P.†
BROOKLYN, NEW YORK

"BE careful of your diet"! How often is this the only dietary prescription given to a sufferer from gastro-intestinal symptoms! If the patient insists on details, he is told to avoid "greasy" foods, "acid" foods, "sweets," red meats" or "starchy" foods, or perhaps is advised against partaking of some food to which the doctor has a pet aversion or an actual idiosyncrasy. When conditions do not improve, is it any wonder that patients seeking detailed instructions based on definite principles, consult the quacks and charlatans who in recent years, in spite of the depression, have been doing a tremendous business, although their theories are fantastic and the results of their treatments in many cases have been disastrous?

The ponderous volumes on dietetics which of late have been published in such profusion have, I believe, done more to confuse the medical practitioner than to help him. If dietetics is such a difficult and controversial subject that it takes one or two thousand pages of text to propound its principles, the average practitioner cannot take the time to make a study of this subject. If the time is available in caring for a given case, search through the books will reveal various, and often entirely different, diets suggested for the disease in question, and a choice will be difficult. If one is decided upon, it means considerable work to make a copy of it for the patient, and when it is all written down some of the foods prescribed may not be tolerated by the patient. This means starting all over again—a task, which, if repeated several times, soon discourages the practitioner from further efforts.

GENERAL DIETARY PRINCIPLES

In order to prescribe a rational diet it is necessary to understand certain principles which must apply to all diets. These principles are well known and need not be discussed here at too great length. They include attention to the caloric value of the food, a proper balance of the essential ingredients, an adequate vitamin supply, a sufficient ash or mineral content and the required amount of indigestible residue and water.

The *caloric value* does not need to be figured out in detail. In fact, in an adult, there are so many factors involved in converting a given number of calories of food ingested into actual available calories in the tissues that a mere statement that a patient is getting two thousand or four thousand calories means very little. The real test as to whether the patient's food contains the required number of calories is the variation in the weight of the patient, and the quantity and type of food will have to be regulated according to this observation.

The *proper balance of the essential ingredients* is often lost sight of when prescribing meat-free, reducing or fat-free diets. Diets deficient in protein are the cause of the debilitated, anemic state of many patients. Insufficient carbohydrate intake supplies inadequate fuel for daily combustion and results in tissue destruction, and insufficient fat, by its failure to stimulate biliary tract emptying, may result in serious gall bladder stasis. The average individual, no matter what his disease may be, requires from sixty to eighty grams of *protein* per day, which must be supplied largely in the form of meat, eggs, cheese, nuts and milk, although a few vegetables, such as beans and peas also contain small amounts of protein. The *carbohydrate* ration, supplied in the form of sugar and the starch of cereals, vegetables and fruits, must depend on the patient's weight and on certain metabolic factors, such as a diabetic state. Where energy must be rapidly supplied, or where liver disease is present, dextrose can be given by mouth, being used in place of saccharose in drinks or other feedings. The *fat* content, also to be governed by the patient's weight, is supplied in the form of butter, meat-fats and oils.

Vitamin deficiency has recently been shown to be the cause of many previously obscure conditions. It seems to play a part in the production of the arthritides, various gastro-intestinal disorders, genito-urinary diseases, and nervous disorders, as well as the previously recognized deficiency states. Ordinarily it may be stated that a diet containing milk, eggs, butter, green vegetables (raw and cooked), raw fruits and whole grains supplies an adequate vitamin supply, but it is probably better, especially during the winter months, to add some extra concentrated vitamin products to the diet of patients whose symptoms might be influenced by vitamin deficiency. Cod or halibut liver oils, viosterol and yeast are usually sufficient.

The *mineral content*, including particularly iron, phosphorus and calcium, is also supplied by the foods mentioned in the discussion of the vitamins, but individual cases may require the addition of an extra supply of one or more of these substances.

Water is one of the most frequently neglected parts of a diet. At least six or eight glasses per day are required to encourage gastro-intestinal digestion and absorption, to supply the water content of the urine, sweat and respiratory tract moisture, and to provide sufficient liquid to keep the feces from becoming too dehydrated.

Indigestible material or *roughage*, including leafy vegetables, skins, pulps and seeds of fruits and hulls of grains, are necessary to provide bulk for the feces. An insufficient quantity of roughage normally results in infrequent bowel movements and should not be the signal for the use of cathartics. Where smooth bulk is desirable, agar or some other similar substance may be added to the diet.

*From the Department of Medicine, Long Island College of Medicine.
†Clinical Professor of Medicine; Chief of the Department of Gastroenterology.
Submitted December 21, 1936.

MECHANICAL EFFECTS OF DIET

In gastro-intestinal diseases great help can be obtained from the diet by considering the mechanical effects of the food on the gastro-intestinal tract. These effects can best be discussed under four headings, as follows:

1. *Soothing* or *irritating* effects must be considered. In cases where the gastro-intestinal mucosa is in an irritable condition as a result of ulceration, inflammation or recent poisoning, a smooth, soothing, emollient diet would be indicated, and such foods as milk, cream, cheese, eggs, well-cooked cereals and puddings, ice cream and gelatin and a minimum supply of condiments should be combined into a well-balanced diet. In cases where the gastro-intestinal tract is in a sluggish or atonic state, as after protracted illness and rest in bed, it may be desirable to combine with the nutritious, well-balanced diet some irritating foods, including meat extractives, condiments, the whole grain cereals and breads, the skins and pulps of fruits and the leafy vegetables.

2. The *bulk* of the diet is important, not only the initial bulk of the feedings but also the bulk of the indigestible residue. Where the stomach is dilated and atonic, small, frequently repeated feedings, by encouraging greater contraction of the stomach in order to empty itself, will often rapidly restore the tone of such an organ. On the other hand, the active, tonic stomach of reflex pylorospasm with retrostalsis can often be made to quiet down by large though soothing feedings, which, if vomited, must be immediately repeated. The bulk of the indigestible materials or roughage must be guided by conditions in the colon. In acute, irritative, ulcerative conditions of the colon a low bulk would be indicated, and a diet almost free or roughage would be desirable. In both the hypertonic or spastic colon as well as in the atonic colon, bulk is indicated, thus giving the colon a definite task to perform, tending to restore normal function. In colonic adhesions and kinks the high-residue diet, by keeping the colon more solidly filled, will prevent symptoms often due to small masses of inspissated feces attempting to pass a narrow point and getting stuck because of insufficient *vis a tergo*. In diverticulosis also, bulky colonic contents will prevent the entrance of irritating liquid material into the diverticula.

3. The *consistency* of the food must be modified according to the conditions present in the esophagus and stomach. Where there is an organic narrowing, cicatricial or malignant, the food should be of a soft or liquid consistency, in order to pass the narrow point. A well-balanced diet, in liquid form, containing milk, cream, eggs, lactose or glucose, cereal gruels and fruit juices, will pass through an almost obstructed esophagus or pylorus and will so improve the patient's general condition that operative or other necessary procedures will no longer be too great a risk. On the other hand, in spastic conditions, such as so-called cardiospasm and pylorospasm, firm, even dry food will often pass the spastic area when liquids would be regurgitated.

4. The *temperature* of the ingested food is of some importance. It must be remembered that the stomach can bring the temperature of ingested cold materials up to body temperature more efficiently and quickly than it can reduce the temperature of hot foods. Liquids, such as beverages and soups, rapidly swallowed and reaching the stomach at excessively high temperatures, are undoubtedly extremely irritating, and in cases of gastric cancer a history of the habit of taking hot liquids is so frequently elicited, that we must consider this source of chronic irritation as a possible etiologic factor. On the other hand, iced drinks or plain ice, in being warmed by the stomach walls, call for a sudden and marked influx of blood and are therefore definitely contraindicated during or soon following a gastric hemorrhage. Cold drinks also, by stimulating peristalsis, sometimes aggravate a diarrhea.

PHYSIOLOGICAL EFFECTS OF DIET

A consideration of the physiological effects of diet is of the greatest importance. The effects of diet on the function of the *esophagus*, for instance, is illustrated by the fact that in the normal esophagus liquids pass more rapidly along its length and into the stomach than solids, whereas in so-called cardiospasm, relaxation of the cardia is encouraged more by solid foods. In the case of the *stomach*, both motility and secretion are affected. Hunger contractions, occurring when the stomach is empty, and markedly increased when ulceration is present in the stomach and duodenum, then becoming perceptible as hunger pains, are relieved by filling the stomach—and keeping it filled—by frequent feedings. Retrostalsis, a more or less mild reverse peristalsis, occurring as a result of irritation of the gastro-intestinal tract from within or without, from stomach to anus, such as ulcer, gall bladder disease, appendicitis, colitis, pelvic conditions or even fissures or hemorrhoids, producing spasm and resulting in the symptoms of epigastric distress, fulness, heartburn, sour eructations, sour regurgitation or even vomiting, is relieved by frequent bulky feedings, which produce more powerful downward peristalsis to overcome the reverse waves. Such a diet would not be successful in actual obstruction, and is often of value as a method of differential diagnosis between spasm and obstruction. In gastric irritability, with increased and prolonged acid secretion, foods which combine readily with hydrochloric acid or do not overstimulate its production, are indicated. Such foods would include milk, eggs, cereals and fats. In the absence of acid secretion, foods which require the action of pepsin-hydrochloric acid on the protein envelopes of their individual cells or fibers, such as uncooked starch and meat, should be avoided or should be properly prepared by adequate cooking or maceration. There is considerable doubt whether condiments or meat extractives will have any effect in stimulating gastric secretion where this is entirely absent, and their irritating effect on the mucosa may easily be detrimental in cases where the anacidity is due to a gastritis. Dilute hydrochloric acid, added to the diet, is of some use in stimulating pancreatic secretion, but is practically of value only in cases where diarrhea accompanies the achylia. It must be remembered that milk, when taken alone, is curdled by the gastric juice into large lumps, whereas when modified by the addition of starch in the form of infant foods or crackers, bread or cake, the curds are small and easily and quickly digested. Gelatin, which acts as a non-irritant protein food, is of value in promoting blood coagulation, and should be remembered in prescribing for cases of gastric hemorrhage.

Biliary tract function can be materially affected by diet. Any foods, but particularly fats, passing through the duodenum, cause relaxation of the sphincter of Oddi at the papilla of Vater, and resultant contraction and emptying of the gall bladder. In conditions of biliary stasis, therefore, frequent feedings, with adequate fat content (preferably not the fat of meat or fowl) tend to clear the biliary tract and tone up the gall bladder musculature. The hypothesis that certain specific foods have more effect on actually promoting liver secretion than have others has not been conclusively demonstrated; any good mixed diet would be of value in this respect. Where there is actual liver damage, animal experiments have demonstrated the extremely harmful effects of meat and meat extractives and the beneficial effects of high carbohydrate feedings. In severe cases, large doses of glucose, orally or parenterally administered, are indicated, and sometimes increasing the tolerance to sugar by the use of insulin is of value.

On *colonic* motility, diet may have either a positive or a negative effect. If a diet free from residue is taken, there will be no effect. Indigestible constituents of the diet, if coarse and irritating, as is bran, will stimulate and improve peristalsis; if smooth and soothing, as is agar, will allay irritation and encourage normal motility. In cases with acutely inflamed, ulcerated and irritable bowels, therefore, a non-residue diet is indicated, whereas in chronic, spastic, irritable conditions, a smooth bulk is desirable, and in atonic conditions, a coarser bulk would be preferable. The bacterial flora of the colon, normally showing almost daily variations, is influenced by the character of the food; a predominance of the acid-forming bacteria occurring in high carbohydrate diets, and of putrefactive bacteria (coli group) in high animal protein diets. It is questionable whether changing the intestional flora is of any value in disease.

ALLERGIC CONSIDERATIONS

Any diet which does not take into consideration the individual idiosyncrasis or the allergic reactions of a patient will usually prove to be inadequate. Most individuals have at least a few of such peculiarities, and if the physician entirely disregards a patient's statements in respect to likes and dislikes may result in embarrassing failure to allay or modify symptoms by diet. It is true that neurotic patients often imagine that certain foods are "bad" for them, when such would really be of value. However, if it is known that a food invariably will produce a skin rash, heartburn, sour regurgitation, an attack of migraine, abdominal cramps or diarrhea, it is well to avoid such a food in prescribing a diet. On the other hand, if a patient is known to be following conscientiously a diet which should produce definitely beneficial results, and these results are not obtained in due time, a suspicion of food allergy must be engendered and search for the food to which the patient is sensitized must be carried out by means of diet study or skin reactions, preferably the former. A readjustment of the diet in accord with information thus obtained will often produce startling results.

PRACTICAL APPLICATION

As examples of the application of the principles which we have been discussing to actual disease conditions, a few typical diets will be presented. In each diet a proper balance of ingredients is an essential consideration.

In uncomplicated *peptic ulcer*, the stomach is irritable, it tends to contract forcibly, making the hunger contractions recognizable to the patient as pain, and there is a tendency to a continued secretion of a hyperacid gastric juice. The diet, therefore, should be bland and smooth, there should be frequent feedings in order to prevent the stomach from becoming empty and the food should combine readily with acid and not too greatly stimulate its secretion. The following diet is the result of the application of these principles:

PEPTIC ULCER DIET

Breakfast:
(8 A. M.)
Milk—1 glass (preferably, the milk should be heated)
Cereal—cooked—3-6 ounces
Egg—one—soft boiled or poached
Bread and butter (or toast)
Juice of orange or grapes (at end)

10:30 A. M.
Milk—1 glass
Crackers, bread and butter or plain cake.

Luncheon:
(1 P. M.)
Milk—1 glass
Eggs or cream cheese
Potato, baked or mashed, or spaghetti (without sauce)
Bread and butter
Pudding, custard, jello or ice cream

3:30 P. M.
Milk—1 glass
Crackers, bread and butter or plain cake.

Supper:
(6 P. M.)
Same as luncheon or breakfast.

8:30 P. M., and at 2 or 3 hour intervals after this if awake:
Milk—1 glass
Crackers, bread and butter or plain cake.

Additions

Yeast may be given early in morning or with meals.
Other vitamine preparations, especially vitamine D, are often indicated.
Iron preparations should be added in anemic patients.
Cream and lactose, glucose or other powdered foods may be added to milk or cereal where patient is underweight.
Olive or cottonseed oil before meals is of value in most cases.
Water, at least 6 or 8 glasses per day, is desirable.

In *Gall Bladder Disease*, the gall bladder is sluggish in its contractions and there is a tendency to stasis of its contents, with increased concentration. Duodenal and gastric retrostalsis produce the distressing dyspeptic symptoms. The dietary indications, therefore, are for normal or excessive fat content, with frequent feedings to act as a stimulant to more complete and *frequent gall bladder* emptying, and fairly large quantities to overcome the retrostalsis. Owing to the

usual liver damage, meat and meat extractives are contraindicated. These principles are fully complied with in the "ulcer diet" and this can be used where an ulcer is coexistent. Otherwise we suggest the following:

GALL BLADDER DIET

Breakfast:
(8 A. M.)
Milk—1 glass (milk, preferably heated)
Cereal—cooked—with cream
Egg—one
Bread and butter or toast
Fruit—raw.

10:30 A. M.
Milk—1 glass
Crackers, bread and butter or plain cake.

Luncheon:
(1 P. M.)
Milk—1 glass
Egg, cream cheese or nuts
Vegetables—cooked—any kind
Salad—any raw vegetables
Bread and butter
Fruit, pudding, jello or ice cream.

3:30 P. M.
Milk—1 glass
Crackers, bread and butter or plain cake.

Dinner:
(6 P. M.)
Same as luncheon.

At bedtime and in night, if awake:
Milk—1 glass
Crackers, bread and butter or plain cake.

Additions

Olive oil and cream are taken with meals, but the quantity must vary according to patient's weight. This is also true of desserts and carbohydrates in general.
Vitamines are usually of value—yeast, fish liver oil preparations and viosterol being the most useful.
In achylia with diarrhea, hydrochloric acid may be indicated.
Water, 6 or 8 glasses per day, is essential.

In *Esophageal* or *Pyloric Stenosis* the narrow lumen will not permit the passage of coarse or bulky foods, yet the secretions are normal and a balanced diet is indicated. The dilated stomach can be stimulated to contract on smaller quantities, frequently repeated, thus restoring its tone. A liquid diet is desirable, and we have the following:

PYLORIC STENOSIS DIET

Feedings at 2 or 2½ hour intervals, each containing
Milk—1 glass
Cream—½ ounce or more
Lactose—½ ounce, or Glucose, ½ to 1 ounce, flavored with chocolate or other flavors as desired.

During a twenty-four hour period there must be added to these feedings:
Eggs—3 or 4 a day
Fruit juice—raw—twice a day
Vitamines—yeast, viosterol, fish liver oils are of value
Minerals—iron and calcium, as indicated
Alcohol—may be added to increase caloric value or as a flavoring.
Water—in esophageal obstruction large quantities are desirable, in pyloric stenosis, in order to avoid increasing dilatation, water should be restricted.

CONCLUSIONS

1. In gastro-intestinal diseases a diet, while essentially prescribed for the purpose of nourishing a patient, must be modified to conform to the required mechanical, chemical and physiological indications.
2. Every diet, and preferably each meal, must contain a proper balance of essential ingredients, a sufficient vitamin and mineral supply, adequate amounts of water, and, unless contraindicated, considerable indigestible residue.
3. The purposes of the diet should be explained to the patient and every detail should be given to him in writing so that misunderstandings or actual errors may be avoided.
4. Changes in the diet should be made only in accordance with certain definite indications, such as gain or loss in weight, variations in symptoms, allergic manifestations and when the causes for which the diet originally was prescribed no longer exist.

The Interrelationships of the Pancreas with Other Endocrine Organs in Diabetes

By

HENRY J. JOHN, M.D.
CLEVELAND, OHIO

IN considering diabetes as an entity, it is customary to think of a deficiency of the insulogenic apparatus, either functional, or caused by actual anatomic changes in the islands. That the problem is not so simple as this has been evident to investigators of the subject for many decades. One has only to recall the frequent incidence of diabetes in connection with acromegaly, the frequency of disturbances of carbohydrate metabolism in hyperthyroidism, the sensitivity to insulin of patients with destruction of the suprarenal glands, the amelioration of diabetes following the menopause, etc., to realize the complexity of these interglandular relationships.

Submitted November 19, 1936.

These are all expressions of some factor aside from insular function of the pancreas which alters the diabetic state either favorably or unfavorably as a result of hypersecretion or hyposecretion of some other gland. For this reason, diabetes is not solely the result of a disturbance of the insulogenic function, but a condition which is affected variably by the direct or indirect action of other organs of internal secretion on the islands of Langerhans.

As the knowledge of this internal interrelationship is being clarified, our understanding of the clinical picture is becoming more complete. Much still remains to be done before we shall be able to utilize all the experimental evidence clinically, but there is good reason to hope for much progress along these lines in the future.

In this summary I have tried to collect some of the facts of this endocrine interrelationship which has a bearing on carbohydrate metabolism. What I have to say does not represent original investigation on my part, and I must apologize that the report is not more complete. In a field which is growing so rapidly, it is practically impossible to keep abreast of all the developments, for new work is being reported almost daily, and what is new today becomes old tomorrow. I have given the references for most of the material, and have quoted freely the statements of some authors, at times interspersing remarks that were pertinent from some other source.

To those working intensively on some phase of endocrine physiology, there will be many gaps in this discussion. For these lapses I hope I may be pardoned, for in a subject as broad as this, one could easily write a book on each separate gland. All that is intended here is a short summary of some of the more recent literature in order to give some indication of the complex interrelationships of the other endocrine organs to the insulogenic function.

THE PITUITARY GLAND

The interrelationship of the pituitary with all the other glands of internal secretion is so well established that it is only to be expected that the pituitary exerts an important influence on carbohydrate metabolism. Since the pituitary also regulates, at least in part, the functions of the liver, the suprarenals and the thyroid gland, each of which also apparently has some direct relation to the regulation of carbohydrate metabolism and pancreatic function, as well as direct relationships to each other, it is obvious that the exact role of the pituitary in these processes is very difficult to fathom. How much of the influence on insulogenesis is direct and how much is accomplished through pituitary influence on other organs is at present almost impossible to determine. I myself feel entirely incapable of interpreting all of the known facts in this connection, and in this short review of some of the clinical and experimental findings I make no attempt to offer any sort of comprehensive explanation.

In *acromegaly* the pancreas often shows degenerative changes of the islands in the pancreas. At other times these are normal. Again, hypertrophy and increase in the number of islands has been reported. (Table 1). According to Atkinson, one-third of acromegalics show glycosuria. The glucose tolerance curve often shows an abnormal rise and a sudden fall into a hypoglycemic level. I performed glucose tolerance tests on fourteen patients with acromegaly (Table 2). Of these 43 per cent yielded a normal curve and 57 per cent a diabetic curve.

A severe diabetes can accompany acromegaly. Some of these patients are reported to be insulin-resistant, and do not react well to dietary restrictions. The sugar excretion can be tremendous, such as is seen in no other disease. (Ravaut, Schmidt, Widal).

Apparently, then, there can be several types of glycoregulatory derangement in acromegaly. There can be real pancreatic diabetes, perhaps due to the excessive output of pancreatropic hormone of the anterior hypophysis. The glycosuria can be caused from a dis-

turbance in the midbrain if the hypophyseal tumor is growing toward the lower part of the brain. In these cases the glycosuria is not excessive and usually is not accompanied by acidosis. In the third place, the carbohydrate disturbance can be of the same nature as it is in hyperthyroidism, if the acromegaly is complicated by a hyperfunctioning thyroid, as the case pictured in Chart 1 would indicate.

The acromegalic patients that I have seen have not been resistant to insulin. In Chart 2, I have depicted two such cases. Both patients were women, one forty-one and the other twenty-one years of age. The response to diet and insulin in both cases was quite prompt. In the first case, a large dosage of insulin was used at first (as much as 70 units a day) which was decreased in a month to 35 units a day. Two years later this patient died in coma as a result of ceasing all treatment. The other patient responded well to insulin and in less than a month all insulin could be discontinued. At the end of a month, the blood sugar was normal, but a glucose tolerance test still showed a diabetic curve. Following this the pituitary was irradiated and repeated checks showed a normal blood sugar level without special diet or insulin.

The third case is extremely interesting. (Chart 3). This patient was a postman, fifty-five years of age, with pronounced acromegaly, who came into the hos-

pital with a fasting blood sugar of 440. He, too, responded promptly to insulin and diet and in less than a month the insulin could be discontinued. Four months later the glucose tolerance test was repeated and was virtually normal. Were one's observations to

stop at this point one would be tempted to say that the patient had been cured of diabetes. I followed him through with a series of glucose tolerance tests for the next four years, and the chart shows the fluctuations of these curves with a normal tolerance curve finally in 1929. Whether these fluctuations are expressions of a periodic hyperactivity of the pituitary as suggested by Cushing I am not in a position to say. Many authors call attention to such fluctuations or remissions of the diabetic state in acromegalic patients. (Table IV).

My impression is that while the mechanism of this type of diabetes is different from that of ordinary diabetes, the treatment remains the same, unless there be surgical intervention or irradiation of the pituitary. If the diabetes is not treated, such patients die in coma, just as any other diabetic patient does. (Table III). There are occasional cures reported, but to be sure of this point, it is necessary to make repeated observations over a period of years.

In *Simmonds' disease* in which there is failure of the anterior pituitary, normal blood sugar and an increased glucose tolerance are the usual findings. Wilder has reported two cases both of which showed clinical signs and symptoms of hypophyseal disease. In both cases there were spontaneous attacks of hypoglycemia.

Boschi reported the results of X-ray treatment of the pituitary in a woman who apparently had severe diabetes. Following the irradiation she ceased to excrete any sugar. I also saw a similar case (Chart 2, second case), but it must be noted that the blood sugar was at a normal level before the irradiation treatments were administered.

Lucke has reported that hypophyseal dwarfs are very sensitive to insulin.

In a series of 106 cases of hypopituitary disease I found a non-diabetic type of curve in 67.9 per cent and a diabetic curve in only 32.1 per cent. (Table V).

Kraus of the Prague Medical School noticed in 1923 that at autopsy, diabetic patients showed hypophyses smaller than normal. The eosinophilic cells were diminished and showed retrogressive changes in the cell nuclei. He followed this observation with experimental work and extirpated the pancreas in cats, thereby producing similar changes in the pituitary.

Muthman has reported the work of Eaves who found morphological changes in the anterior lobe of the pituitary which suggested a hyperactivity of the gland following the administration of insulin to a rabbit.

Houssay and Biasotti have shown that in hypophysectomized dogs and other species the removal of the pancreas was not followed by glycosuria. The administration of sugar, however, caused excretion of part of the sugar and an increase in the respiratory quotient. The implantation of the pituitary in these same animals produced diabetes. Davis also ascertained that bilateral hypothalamic lesions followed by pancreatectomy do not produce hyperglycemia and glycosuria.

Anselmino and Hoffman feel that they have proved basically that diabetes mellitus in the human being is occasioned by a disturbance of the pituitary regulating mechanism. As to the mechanism of the action of the pancreatropic substance derived from the anterior lobe of the pituitary, Hoffman and Anselmino reported on a number of insulin-like effects on metabolism which were lacking in dogs without a pancreas. They concluded that the effects on metabolism are to be attributed to an increase in secretion of insulin under the influence of the pancreatropic substance of the anterior lobe of the hypophysis.

Cowley has suggested that in hypophysectomized animals these effects may be due to the unopposed action of insulin.

The diabetogenic substance, according to Collip, can be studied to best advantage in the Houssay dog, that is, in the depancreatized-hypophysectomized animal which becomes, according to Barnes and Regan, very sensitive to insulin and can have hypoglycemic convulsions during fast. When the blood from such an hypophysectomized dog is injected into rabbits it causes a fall in the level of the blood sugar. The hypophysectomized-depancreatized animal shows no glycosuria but often an injection of the pituitary extract produces glycosuria and hyperglycemia. Pituitrin does not produce glycosuria but the injection of whole gland extract will produce it. The acid extract of the anterior lobe, however, produces much more pronounced and persistent glycosuria. When the thyroid is removed, some of the dogs do not show glycosuria under these circumstances.

Weed, Cushing and Jacobson, upon stimulating the superior cervical sympathetic ganglion in animals produced glycosuria. They reasoned that this was effected by the liberation of the hormone through impulses which reached

the hypophysis. They concluded that it is likely that the carbohydrate hormone comes from the chromophilic cells.

Cope and Marks removed the pituitary in animals and the adrenals responded normally to insulin hypoglycemia by liberating epinephrin into the blood stream, but the

epinephrin failed to restore the blood sugar to a normal level in spite of ample reserves of liver glycogen. The hyperglycemic response to injected epinephrin was likewise diminished. Reverse changes were noted, namely resistance to insulin and an increased response to epinephrin when extracts of the anterior lobe of the pituitary were administered. They feel that the anterior lobe of the hypophysis contains a principle which renders the glycogen stores of the liver and possibly those of the muscles susceptible to the mobilizing action of epinephrin. The changes following removal of the hypophysis can not be reversed by the administration of thyroid and hence they are not due to the concurrent thyroid degeneration. The changes produced by the injection of anterior pituitary extract are not prevented by the removal of the thyroid.

Lucke and Hahndel, who studied the mechanism of the action of the contra-insular hormone of the anterior lobe of the pituitary came to the conclusion that its point of attack is in the central nervous system and that the activity of the adrenal system is guided by the hormone from the central system by way of the sympathetic nerve pathway. The mechanism of action corresponds in principle to that observed in a condition of diabetes produced by puncture.

Dogs without their suprarenals are very sensitive to insulin even in states of normal glycemia. The level

of the blood sugar does not rise after the injection of the contra-insular hormone in dogs without adrenals. This shows that the adrenals must be involved in the action of the contra-insular hormone of the anterior lobe of the pituitary. Regarding the exact mechanism of action, there are two possibilities: Either the contra-insular hormone formed in the anterior lobe acts directly on the adrenals from the blood system, or through the central nervous system, and the stimulus is relayed to the adrenals by way of the sympathetic nerve tract, thus setting up conditions analogous to the mechanism of action in puncture diabetes.

Animals with denervated adrenals are sensitive to insulin and display an intense increase in the level of blood sugar after the injection of epinephrin. The required hormone equilibrium for the normal maintenance of carbohydrate metabolism in the face of distorted island function of the pancreas can only be effected by the influence of the anterior lobe of the pituitary and by an intact suprarenal pathway.

THE THYROID GLAND

Hyperthyroidism is one clinical condition in which I have had the opportunity to make rather thorough studies of carbohydrate metabolism. The clinical data from my own series and others reported in the literature are now large enough to make some statistical analysis. These show a greater incidence of diabetes in hyperthyroidism than the average, namely 2.31 per cent, in a series of 20,325 cases which I collected in 1932. This is not a huge incidence, but still it is about twice that of diabetes generally. The problem which confronts the clinician is to determine the factors involved and to decide whether any safeguards can be provided to prevent this increased incidence of diabetes in hyperthyroidism.

We know that in hyperthyroidism the liver function is deranged. The liver is poor in glycogen and can not fix glycogen normally. This would be sufficient explanation for the non-physiologic hyperglycemia, but it does not explain the development of diabetes in these patients. Can it be that these patients, because of increased metabolism, consume enormous quantities of food and especially of carbohydrate, and hence place an extra load on the insulogenic function, which may thereby become exhausted, especially if there has been some preexisting "diabetic anlage"? This may be one logical explanation. We know that it is not merely the increased metabolism which is responsible for the hyperglycemia, for if it were, hyperglycemia would be present in the majority of severe cases of hyperthyroidism. Yet this is not the case. Furthermore, were the hyperthyroidism alone responsible for the disturbance in carbohydrate metabolism then certainly such a disturbance would run parallel with the severity of the hyperthyroidism, which also does not conform with the findings. The increase in basal rate, too, bears no relation to the degree of hyperglycemia. Often the mildest thyrotoxicosis produces the most profound dysfunction of carbohydrate metabolism, and on the other hand, the patients with the highest level of blood sugar may respond most promptly and permanently to treatment and often are completely cured. This proves that there are adequate safety factors in the human body.

However, it is impossible to determine beforehand which of these disturbances during hyperthyroidism will right themselves and which will develop into instances of permanent diabetes. In some cases in which there is but slight indication of disturbed carbohydrate metabolism the condition is apparently corrected after thyroidectomy, with no evidence of abnormality for a year or more, and yet later these patients may become severe diabetics. Chart 1 shows such a case.

This patient was a young woman, twenty-six years of age, with severe hyperthyroidism. Her basal metabolic rate was plus 57 per cent. The only thing which led to the investigation of the carbohydrate metabolism was glycosuria which she had on successive days along with normal levels of blood sugar. The glucose tolerance test showed a diabetic curve, and still the daily fasting blood sugar level after this was normal for over a month. Two months after thyroidectomy the glucose tolerance test was repeated and it still showed an abnormal curve. Two more fasting blood sugar determinations three months later were normal. The third glucose tolerance test, seven months after thyroidectomy, showed some improvement, but still gave a prediabetic curve. However, the blood sugar was normal, morning and noon, on the following day.

I did not see the patient again until recently when she was sent to me because she had diabetes which her physician could not control. Her subsequent story is shown on the chart. She has severe diabetes now, five years after

the thyroidectomy, and this condition evolved from the mildest sort of carbohydrate disturbance during hyperthyroidism.

It brings out the point that clinically we can not afford to disregard deviations in carbohydrate metabolism during hyperthyroidism. Similar and more dramatic stories I could present by the score.

It was known almost a century ago that persons and animals with endemic goiter develop hypertrophy of the anterior lobe of the pituitary gland. Thyroid enlargement and hyperactivity with acromegaly have long been noted. It has also been known for a long time that the thyroid acts as a depressant of the insulogenic function. Only recently, has it been demonstrated that the administration of desiccated thyroid prevents this pituitary effect and furthermore that the acidophilic granules of the anterior lobe produce a thyroid-stimulating principle, which causes hypertrophy of the epithelial cells of the thyroid vesicles with an increase in thyroid secretion.

Shockaert has induced enormous hypertrophy of the duck's thyroid accompanied by exophthalmos by the injection of extracts of the anterior lobe of the pituitary. Experimental exophthalmos can be produced readily by injections of pituitary extract into thyroidectomized animals. Houssay has carried out experiments with dogs which clearly indicate that the pituitary influence controls the thyroid in these animals.

TABLE V

Glucose tolerance curves in hypopituitarism (John).

Type of Curve	Non-diabetic		Diabetic	
	I	II	III	IV
Number of cases	36	36	27	7
Per cent	33.9	33.9	25.5	6.6
Glycosuria, cases	6	15	13	7
Per cent	16.6	41	49.6	100
No glycosuria, cases	30	21	14	0
Per cent	83.4	59	50.4	0

Since the thyrotropic hormone causes an increased activity of the thyroid gland which in turn increases the metabolism, we can rightfully expect an increased demand on the insulogenic function. The secretion of insulin keeps pace with this demand so long as the pancreas is intact, but if it is not, there is evidence of insulin deficiency, which manifests itself as a non-physiologic hyperglycemia. Another explanation for non-physiologic hyperglycemia in hyperthyroidism would be a direct neutralization or depression of the insulin action by the excess thyroid secretion.

There is still another possible explanation for hyperglycemia in hyperthyroidism. We know that certain infections produce diabetes and that already existent diabetes is much aggravated by an infection. The toxemia with its accompanying acidosis probably is the damaging factor. In the normal person, the level of aceto-acetic acid never exceeds 3.5 mg. per cent and that of beta-oxybutyric acid, 5.5 mg. per cent. In the thyrotoxic patient, these values are high, 16 mg. per cent for aceto-acetic acid, and 18 mg. per cent for the beta-oxybutyric acid. Hence the toxemia of hyperthyroidism might account for the damage to the islands.

The degree of liver derangement probably goes hand in hand with the severity and duration of the hyperthyroidism, and yet there is no consistent change in the glucose tolerance curve to correspond to this.

The thyroid is regarded as a depressant of insulogenic function, and yet it is likely that this is not due to the direct effect of the thyroxin on the islands of Langerhans, but reversely, to the direct effect of insulin on the thyroid. Both hormones exert their effect on the liver, muscles and the carbohydrate metabolism, partly supporting each other, partly increasing the common utilization of these hormones. If one or another part of this synergistic whole is out of balance, this would explain why in some cases of hyperthyroidism there is an increased utilization of sugar, and in others a decreased utilization.

I feel more and more that when diabetes develops in a patient with hyperthyroidism, a diminished insulogenic reserve must have been present beforehand.

THE SUPRARENAL GLANDS

The relationship of the suprarenal glands to carbohydrate metabolism has been known for a long time. Clinically, in Addison's disease, the blood sugar level usually is low, and in suprarenal tumors in which there is an excess of adrenal secretion, the blood sugar level often is increased.

An increased quantity of insulin in the blood stream seems to release more epinephrin (Kugelmann). Excessive output of insulin induces enlargement of the cortex (Hartman). Animals without the suprarenals are much more sensitive to insulin than normal animals. Experimental diabetes is much less marked in the presence of adrenal insufficiency than in normal animals. This is due at least in part to the absence of the cortical hormone (Hartman and Brownell). In suprarenal insufficiency the glycogen is slowly regenerated after severe fatigue (Dambrost). In late stages of insufficiency the liver and muscle glycogen are much depleted and the blood sugar usually falls.

In 1901 the discovery by Blum that the injection of epinephrin was followed by hyperglycemia and glycosuria, gave rise to the theory that this substance was the physiologic antagonist of insulin. That same year Zuelzer demonstrated in a rabbit that the blood sugar level rises as high as 700 mg. per cent and higher. Dogon in 1904 found that the glycogen in the liver is decreased so that after a larger dose of epinephrin the liver can become glycogen-free. Velich, Blum and others found that the intensity of the adrenalin hyperglycemia and glycosuria depends on the glycogen quantity of the liver. If the liver is made glycogen-free the blood sugar will not rise after adrenalin injection. It was Velich who first proved that the adrenalin glycosuria is not caused by pancreatic insufficiency. The Vienna school built up an elaborate theory of glandular interrelationships between the thyroid, adrenal medulla and the pancreas to explain the effects of pancreatectomy. This view has come to be known as the "overproduction theory." The main thesis is that the diabetic condition is not entirely brought about by a failure to metabolize glucose, but rather by an overproduction of this substance from protein and fat. On the basis of the glycosuric action of epinephrin, they argued that the uncompensated action of the adrenal medulla in the absence of the pancreas brought about this overproduction. In brief, according to this theory, diabetes mellitus was in reality hyperadrenalism (Long).

The work of many investigators has exposed the false-

ness of this view. In the first place, epinephrin, although producing glycosuria and depletion of liver glycogen, does not stimulate protein metabolism nor does it produce the degree of ketonuria that is present in diabetes. Nor does its continued injection produce a persistent glycosuria such as is seen in the fasting animal. The more recent work of Cori has demonstrated that epinephrin, although at first reducing liver glycogen, finally brings about a marked increase in this substance at the expense of the muscle glycogen. It would appear at the present time that the effects of epinephrin are limited to the formed carbohydrate elements in the body and that it is incapable of stimulating the production of glucose from protein.

In hypophysectomized animals the suprarenals show an atrophy which is limited to the inner layers of the cortex; the medulla remains intact (Long). Barnes and his coworkers in their studies upon the effects of suppression of epinephrin secretion upon pancreatic diabetes in dogs found that such a procedure may produce some amelioration of the diabetes, but this effect is inconsistant. Of greater interest is their finding that the insulin required to maintain such animals is often only a fifth or a quarter of the quantity required when the adrenal medulla is active. If epinephrin is infused at a physiologic rate into such animals the insulin requirement promptly returns to normal.

DeTakats and his associates have shown that section of the splanchnic nerves, coeliac ganglionectomy or denervation of the suprarenals results in a decreased insulin requirement both in dogs and in human diabetics. In interpreting these experiments it should be remembered that epinephrin does not alter the nitrogen metabolism and there is a good reason for believing that its effects are limited to the formed carbohydrate stores of the body (Long).

Britton, Zwemer and others have shown that the marked hypoglycemia and low liver glycogen stores of adrenalectomized cats are relieved by the injection of cortical extracts that will maintain such animals in good health.

Long and his associates removed the suprarenals and the pancreas in cats; these animals were injected daily with cordical extract, but no insulin was administered. The effect of total suprarenalectomy upon pancreatic diabetes they found was strikingly similar to that of hypophysectomy. Hyperglycemia and glycosuria were much reduced; nitrogen excretion and the D/N ratio were decreased; ketonuria was very slight and acidosis did not develop; the survival period of the animals was much increased; hypoglycemia was common. There was occasionally some improvement of carbohydrate tolerance but this was not so marked as in the Houssay dogs. In another series of experiments they have shown that it is the adrenal cortex and not the medulla that is responsible for these changes, since animals from which the adrenal medulla is removed rapidly die of diabetes after pancreatectomy. These authors suggested that the hypophysis controls sugar formation from protein through the adrenal cortex. This they say is tantamount to saying that the adrenal cortex contains a diabetogenic substance or a contra-insulin hormone.

LIVER

Claude Bernard originally considered glucose as an internal secretion of the liver, differentiating it from bile, the external secretion of the liver. From this ingenious observation there arose a whole series of teachings about internal secretions which in time eliminated from consideration that very first representative, glucose. More intensive study and increased knowledge of metabolism, however, showed that Claude Bernard's definition had a healthy kernel, even though the sense today differs from that understood by its author.

The regulation of the blood sugar level is not a simple, but a complex affair. Hyperglycemia *per se* stimulates the pancreas to production of insulin for its control. Hypoglycemia, on the other hand, stimulates the secretion of epinephrin which releases glucose from the liver to counteract the hypoglycemia. The Kupfer cells in the liver also play no small part in the regulatory mechanism of carbohydrate metabolism and the blood sugar level, as shown recently by Althausen and his associates. The secretion of insulin is regulated by means of a nervous mechanism and also through a humoral mechanism. Both regulatory mechanisms are activated by the glucose itself, even in small concentrations and thereby its action can be considered purely hormonal. The suprarenal factor depends on the blood sugar level, which, if lowered below a certain point, calls forth an increased production of epinephrin from the medulla, but this occurs only if the splanchnic nerves are intact. If these nerves are severed or if their function is prevented by ergotamin, such a reaction does not take place. The transfusion of hypoglycemic blood, activating the nerve centers dealing with the blood sugar regulation also calls forth adrenal secretion only if the innervation of this gland is intact.

It is also possible that the changes in the level of glucose give rise even in the tissues themselves to a regulatory mechanism. In this manner certain finer differences in the concentration are regulated which, however, are insufficient to cause marked stimulation of the larger mechanisms. Charvat and Gjuric in their studies of the relationship of the arteriovenous differences of blood sugar in normal persons, diabetics, and patients with hyperthyroidism, found upon injection of normal saline that when the tissues have a marked avidity for sugar, such as in hyperthyroidism, a slight stimulation with very small quantities of sugar in the arterial circulation is enough to cause almost immediately its fixation and finally even its oxidation, so that the level in the venous blood is lowered. This occurs much earlier than the reflex stimulation of insulin secretion which, as Pollack first showed, takes place about a half hour after the ingestion of glucose.

In all cases glucose acts directly or indirectly as a regulator and for that reason the liver is classed in the endocrine system as an organ maintaining hormonally the standard circulation of glucose, a substance necessary to life. Furthermore, glucose has a typical hormonal function in that, according to its concentration, it produces varying effects, which is true of other hormones. It is also known that glucose is a mighty protector of the liver cell, as Mann, Bollman and others have shown.

Another function of the liver which is closely connected with the glycoregulatory problem, is the production of glykaemin. Glykaemin is a special hormone which dializes through a living membrane, is soluble in alcohol and causes a rise in blood sugar through the prevention of the fixing ability of the sugar in the tissue and liver cells. This in turn increases the sugar output of the liver and hyperglycemia results. It was through the clever work of O. Loewi and his pupils, Hasenöhrl, Depisch, Ueberrack, Högler and Thomann that it was demonstrated that the diabetic glycoregulatory derangement is caused by the primary inability of liver cells to fix the circulating sugar. In their study of the reasons for this, they found that it

was not the inadequacy of insulin in itself, but the presence of some special substance which prevented the cells from fixing the sugar. In this case it was the red corpuscles. This substance, glykaemin, is a direct antagonist of insulin, and is manufactured under certain conditions by the liver. It can be washed out by means of adrenalin from the liver, it is present after the sympathetic stimulation of the liver, it is found after a heavy carbohydrate diet. Its production is depressed by insulin and it is found in the blood stream after extirpation of the pancreas. Under certain conditions it is produced by insulin hypoglycemia, probably through some interaction of the suprarenals, in which case it appears as a compensatory mechanism (Högler, Thomann and Ueberrack). It is formed in the liver and can be found in the hepatic vein, after adequate stimulation, earlier than in the rest of the circulation.

Normally it is present in very small quantities in the blood stream and its effect is disguised by insulin. If sugar is administered orally, the glykaemin output as well as the insulin output is increased. In the normal individual insulin soon dominates. If the innervation of the pancreas is interrupted either by atropin or vagotomy the effect of glykaemin can be

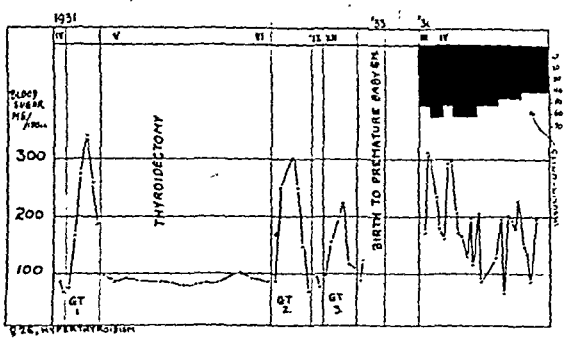

Chart 1. Blood sugar studies in a case of hyperthyroidism showing glycosuria and a slight carbohydrate metabolism during the hyperactive stage which cleared up following thyroidectomy only to reappear five years later as severe diabetes.

seen after a glucose meal. In the fasting state, the effect of glykaemin can not be noted because the pancreas can adequately counteract it and control it.

Minkowski and Allen have shown that if one-tenth of the pancreas is left in the animal, diabetes is not produced and Pollak has stated that in man if the insular apparatus is reduced by one-half, severe diabetes supervenes. Loewi explains this difference by the fact that in human diabetes there is primarily some sort of liver damage which leads to an increased secretion of glykaemin. Because of this, the pancreas is kept at a constant level of compensatory hyperfunction and thus finally becomes exhausted.

The internal secretion of the pancreas is necessary for the proper functioning of the liver. Following the extirpation of the pancreas, the liver not only loses all its glycogen, but undergoes fatty degeneration and functional deterioration.

These problems are very complex and the only thing I wish to show is how closely the liver is connected with the hormonal function of the pancreas. On the other hand, without the liver, the islands of the pancreas lose their "raison d'etre" for even though the insulin then can function in the periphery in the fixation of the sugar in the tissues, it can not increase the oxidation of the sugar in the body, which is necessary to maintain one of the basic functions of life. Through this hepatopancreatic correlation, the liver is entrenched firmly in the endocrine family.

THE SALIVARY GLANDS

Many clinical observations and considerable experimental work has been done in the past decade in an effort to learn the true function and significance of the salivary glands. In spite of the tremendous amount of work that has been done on this problem, the question as to whether or not the salivary glands have an internal secretion has not yet been answered satisfactorily. Considerable clinical and experimental evidence has accrued to indicate that there probably is an indirect, if not a direct relationship between the salivary glands and various glands of internal secretion (Charvat, Bauer, Römer).

In 1897 Ferrannini reported a case of salivary diabetes, in which glycosuria alternated with and replaced the glycosialorrhea. This case suggested a possible reciprocal relationship between the salivary glands and the pancreas. On the basis of experiments with extracts of the salivary glands, Farroni, who was Ferrannini's assistant, postulated an endocrine action of the salivary glands analogous to that of the pancreas.

A decade later, Best, Scott and Banting found much insulin in the salivary glands, which they thought was due to extravasation from the blood stream. Glaser and Bannet analyzed chemically a few kilograms of salivary glands and did not find insulin but demonstrated the presence of peroxydases and oxydases, which might replace the secretion of the pancreas in some cases.

Utimura found that after parotidectomy the action of the thyroid was increased, the islands of Langerhans were enlarged, and there was an increase in the amount of liver glycogen. When the submaxillary glands were removed, these changes were reversed, and if both parotids and the submaxillary glands were extirpated there were no changes in the pancreas and the liver.

Mansfeld and Schmidt ligated the parotid glands of dogs, and found that the level of the blood sugar was lowered. Later, the ligated glands were extirpated and the level of dextrose returned to normal. In dogs with experimental diabetes, produced by partial removal of the pancreas, ligation of the parotid ducts controlled the hyperglycemia. However, ligation of the ducts of Steno had no effect in controlling the diabetes produced by total removal of the pancreas. Mansfeld concluded from these observations that the parotid glands must produce a substance which stimulates the pancreas to increased function. Seelig and also Dobrzaniecki and Michalowski repeated Mansfeld's experiments and confirmed his observations.

In 1932 Zimmermann made similar studies and also made extensive histologic studies of the parotid glands removed at varying intervals after ligation. Goljanitsky also made comparative histologic studies of the pancreas and the parotid. He felt that the internal secretion of the salivary gland has a function similar to that of insulin and that both hormones are antagonistic to epinephrin.

As a result of these experiments on animals, numerous attempts, (Goljanitsky, Seelig) have been made to treat diabetic patients by ligation of the parotid ducts, but the results have not been sufficiently encouraging to warrant any wide application of the method.

Parotid swelling during mumps accompanied by a tenderness in the pancreas is not a rare finding. The development of diabetes following epidemic parotitis too is

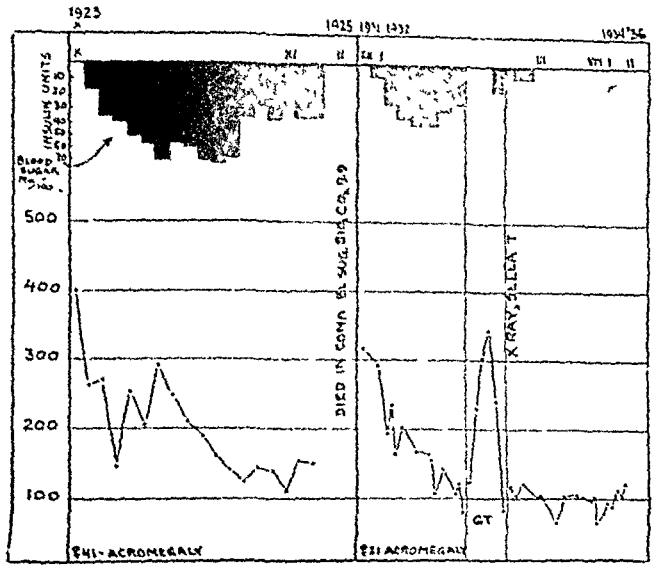

Chart 2. Two cases of acromegaly with observations on the blood sugar in each. One died in coma, the other cleared up and stays cleared up on normal diet.

not uncommon. The cases in children that I reviewed in 1934 from among my own series and those gathered from the literature totaled twenty-eight. In these cases it is difficult to say whether the damage was primarily in the pancreas or whether impairment of parotid function had some bearing.

In 1932 Charvat reported three cases of mild diabetes in which there was also a symmetrical painless non-inflammatory swelling of the parotid glands, which had persisted from six months to three years. He felt that the parotid swelling represented a compensatory hyperplasia of the glandular parenchyma in response to failing insulogenic function or a symptom of endocrine hyperfunction of the salivary glands, which might account also for the mildness of the diabetic state. In two of these patients, the parotid swelling decreased with treatment for the diabetes.

Flamm became interested in the study of hypertrophy of the parotid glands as a symptom of diabetes through observing a woman with hypertension who had frequent attacks of swelling of the salivary glands, which were not accompanied by pain, fever or other signs of inflammation. In the intervals between attacks, the parotid glands remained somewhat larger than normal. Later diabetes was discovered with continued recurrence of parotid hypertrophy. This caused a peculiar transformation of the features of the face, which Flamm noticed was quite characteristic of a good many patients with diabetes.

In a group of twenty-seven patients with swelling of the parotid glands, sixteen showed glycosuria and also an increase in the fasting blood sugar. Dextrose tolerance tests showed some decreased tolerance in the other eleven patients. He also noted that most of these patients belonged to the constitutional type designated as asthenic hypertension diabetes. Flamm offered no direct explanation of the functional processes underlying this hypertrophy of the parotids in diabetic patients, but concluded that it might be interpreted as a compensatory process.

In 1933, I published observations on four patients with enlargement of the parotid glands and mild diabetes. Recently I have seen another case of this type. None of these patients sought medical advice because of the diabetic condition, although in one case diabetes had been diagnosed previously but the patient had not had adequate or systematic treatment. In each instance the enlargement of the parotid glands was noted on the clinical examination with subsequent detection of glycosuria and hyperglycemia. In none of these cases could the parotid hypertrophy be attributed to any inflammatory or infectious process. All five patients were obese and there was a striking similarity in their facial appearance. The diabetes was mild in all these cases and was easily controlled with moderate dietary restriction and small doses of insulin. Whether the parotid swelling represents a compensatory process brought about by a decreased pancreatic function, as Charvat and Flamm have suggested, remains an open question. At present I feel that this problem is largely of academic interest until such time as the internal secretion of the parotid can be isolated and its function determined.

THE PARATHYROID GLANDS

There is but little evidence of any direct association between the function of the pancreas and of the parathyroids, although temporary glycosuria of the alimentary type has been reported in cases of idiopathic tetany. However in tetany the carbohydrate metabolism does not manifest the same disturbance in all cases. Charvat says that at times he has found very low glucose tolerance curves, and at other times the glycemia is pronounced, and in one case he found glycosuria. The variation is probably because there is rarely a disturbance of a single gland, and these bizarre findings are for the most part the result of pluriglandular dysfunction.

Despite these inconclusive clinical findings, we do know that there is a definite and important relationship between carbohydrate metabolism and phosphate metabolism. Retention of phosphates is an outstanding metabolic feature in parathyroprival tetany. In parathyroid insufficiency the blood phosphates are increased and the urinary phosphates are decreased, as shown by McCullagh. In 1932 I reported a study of phosphate curves made along with blood sugar curves during glucose tolerance tests. When the sugar curve increased, the phosphate curve decreased, and vice versa. Harrop and Benedict, who reported similar studies, believe that phosphates are utilized temporarily during the transference of glucose from the blood.

Experimentally in tetany or parathyroid insuffi-

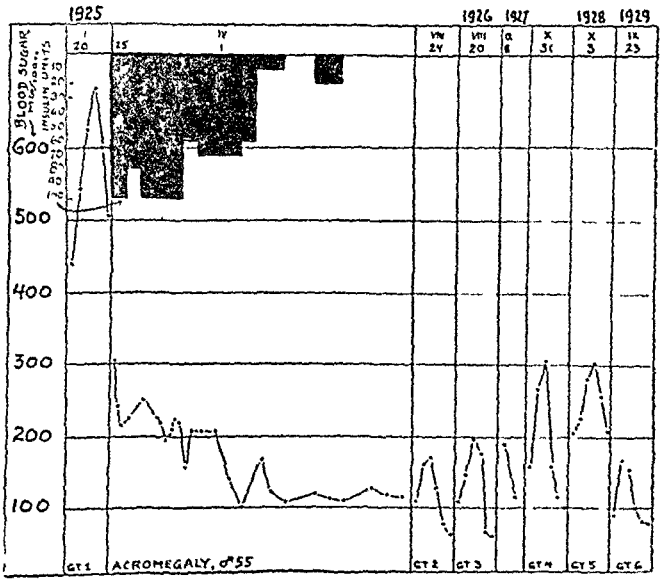

Chart 3. Blood sugar studies on a case of acromegaly, who shows periodic recessions of his diabetic condition.

ciency there seems to be insufficient fixation of sugar in the liver and in other instances there is a glycoregulatory disturbance. Houssay and Biasotti report marked degenerative changes in the parathyroids in the hypophysectomized, pancreatectomized animals. A dependence of the parathyroids upon the anterior pituitary seems rather clear in some species (Hertz, Houssay) but the evidence for a specific pituitary hormone with a direct action on the parathyroids is relatively scanty.

THE GONADS

That the sexual function is influenced by and also exerts an effect on carbohydrate metabolism is well known clinically. The relief of diabetes in many cases following the climacteric has been observed by every specialist in the field. The failure of menstruation and of all reproductive function in cases of severe diabetes not controlled by insulin is also a matter of common knowledge. The lowered glucose tolerance in many pregnant women has also been observed frequently. In some of these instances, the disturbance is corrected after delivery, and in others, frank diabetes may supervene. It is difficult to say whether in these cases the patient had a decreased insulogenic reserve to start with, or whether other factors are responsible.

The actual incidence of diabetes in the eighth and ninth decades is comparatively rare. According to Eiselt such patients are insulin resistant. Arteriosclerosis is a common finding in this group and pathologically there are interlobular and intralobular changes in the pancreas along with atrophy and sclerosis of the islands of Langerhans, according to Weischselbaum. Just what endocrine changes, especially gonadal changes, play a part here is very difficult to state, because there is probably a general subnormal function of all these organs.

It is well known that the withdrawal of the ovarian or testicular hormone causes marked changes in the anterior lobe of the pituitary, and it is probably through the influence of this disturbed pituitary function that other bodily changes occur. No very conclusive studies of the carbohydrate metabolism in eunuchs has been made, and so the effect on the pancreas of the withdrawal of the sexual hormones is extremely difficult to determine.

There are evidences, however, that the insulogenic function is somewhat disturbed. Charvat has reported lowered glucose tolerance curves in eunuchs. However, in obese eunuchs he found that the glucose tolerance was increased. A small group of glucose tolerance tests which I made on castrates showed invariably either a normal or an increased tolerance. This, however, does not prove anything, for to judge and to evaluate such cases would require a large series, and what is more important, a controlled series. Glucose tolerance tests should be done before castration and then followed with repeated tests each year or so following gonadectomy. Such data I have not been able to find in the literature.

(An extensive bibliography had to be omitted for lack of space—Editor).

Blood Pressure Changes During Defecation

By

EDMUND W. KLINEFELTER, M.D.

YORK, PENNSYLVANIA

DURING the year 1931 in the course of my practice I attended six patients who expired suddenly from cerebral hemorrhage. Death occurred in these patients while they were on the toilet seat attempting to move their bowels. All of these patients had been affected with hypertension and constipation. The conclusion seemed likely that there must exist some relationship between these deaths and hypertension associated with constipation.

A consideration of this relationship suggested the questions: (1) during the act of defecation does a rise in blood pressure occur? (2) what is the average rise, if such a rise does occur? (3) is there a relationship between the blood pressure and the degree of straining? (4) can the change in blood pressure be sufficient possibly to threaten rupture of a blood vessel wall? (5) during defecation are different diseases associated with specific blood pressure changes?

In view of the fact that a search of the literature disclosed no answers to these questions, since 1931 I have examined over 300 male patients. I have measured blood pressures in the usual manner. These blood

Submitted August 1, 1936.

TABLE I

Type of Patient	No. of Patients Examined	Average Age	Average B.P. Before Defecation	Average Increase in B.P. During Defecation	Highest B.P. Increase After Maximal Stress
Normal B. P.	90	38	115 70	20 15	110 80
Hypertension	70	60	160 95	25 15	100 70
Obese, 15 or more lbs. overweight	40	50	125 85	15 10	70 40
Underweight, 10 or more lbs.	25	45	120 75	25 20	90 70
Chronic Myocarditis Not Decompensated	20	62	130 85	20 15	60 20
Asthma	15	35	120 75	15 10	40 30
Hyperthyroid	10	29	135 70	15 15	70 60
Angina Pectoris	10	57	125 85	20 10	60 30
Diabetes	10	45	120 85	20 15	100 70
Chronic Pulmonary T.B.	8	34	110 65	20 10	40 40
Hypothyroid	5	35	110 70	20 15	80 60

pressures were recorded while the patient was sitting on a toilet seat engaged in moving his bowels. The results are summarized in Table I.

COMMENT

Table I shows a significant rise in blood pressure during defecation. With a corresponding degree of stress, this rise averaged 20/15. But the greater the degree of stress, the higher the rise in blood pressure. In one patient this effort produced an increase amounting to 110/88. Certainly an increase in blood pressure such as this would appear to add considerably towards the danger of rupture of a diseased blood vessel wall.

Examination of patients affected with different diseases as shown in the Table revealed nothing specific, the blood pressure changes not differing markedly from the average. Alterations of blood pressure in disease seemed different only in so far as the disease interfered with the ability to strain.

CONCLUSION

The act of defecation is attended by an increase in blood pressure. This increase in blood pressure is greater according as the straining at stool is greater.

Etiology of Gall Stones:

II. *The Relationship of the pH of Bile to the Formation and the Dissolution of Gall Stones**

By

MAURICE FELDMAN, M.D., SAMUEL MORRISON, M.D.

and

JOHN C. KRANTZ, Jr., Ph.D.†

BALTIMORE, MARYLAND

WHILE pursuing experimental studies on the etiology of gall stones, it became apparent that a change in the pH of bile was one of the most important factors in the formation of stones. A survey of the literature reveals but little data regarding the pH of bile in animals or human subjects. Most of the available data are concerned with the pH of dog's bile. In a previous study, the authors (1) as well as others, noted that human stones placed in a dog's gall bladder would dissolve. The explanation of this observation will be considered below. On the basis of this finding in the dog, a study of the pH of bile in other animals was made. Nichols (2) observed that the bile of guinea pigs is alkaline to litmus but the pH was not determined by the electrometric method, since this method was not available at that time. In a recent communication (1), the normal pH of guinea pig's bile was stated to average 8.89 in 26 specimens. Since this report we have examined 45 specimens and found the hydrogen-ion concentration to range from 8.66 to 9.14 with an average pH of 8.93. The hydrogen-ion concentration in our studies was determined electro-

†Respectively, Assistant Professors of Gastro-enterology and Professor of Pharmacology.

metrically, using the Wilson type hydrogen electrode (3) at 25° ± 0.5° C.

Since it is now well established that human gall stones will dissolve in the normal gall bladder of dogs and inasmuch as it is our impression that a change in the pH of bile is an important factor in this dissolution, further proof of the effect of pH upon stones suggested itself. This information might aid not only in the understanding of this dissolution but might also reveal the mechanism of the formation of stones.

TABLE I
Controls

pH	Weight of Stone Grams Before	pH	Weight of Stone Grams After	Number of days after implantation of stone in gall bladder
8.88	0.044	8.80	0.043	110
8.70	0.034	8.56	0.028	114
8.90	0.045		0.044	112
9.07	0.038	9.00	0.035	112

8.92	0.039	8.88	0.039	112
8.85	0.038	8.80	0.032	114

EXPERIMENTAL

Human gall stones of the cholesterol type were placed in the alkaline bile of seven guinea pigs; the results obtained are tabulated in Table I. The pH determinations were made on bile obtained by needle puncture prior to opening the gall bladder and each stone, after drying to a constant weight, was weighed and placed in the gall bladder. This table indicates quite strikingly that gall stones are not affected by the guinea pig's alkaline bile even after a long period of time. It also demonstrates that practically no change occurs in the pH of the bile owing to the presence of stones.

This suggests that if one could change the pH of the guinea pig's bile from alkaline to acid by chemical means it might be possible to bring about dissolution of the stones. Seven guinea pigs were therefore given a ten per cent solution of sodium dihydrogen phosphate in large doses. In four, normal control guinea pigs were used and in three, stones were placed in the gall bladders. Table II presents the findings of this experiment. It will be seen that no significant change in the pH or in the weight of the stones took place, indicating that a solution of ten per cent sodium dihydrogen phosphate administered orally had no demonstrable effect upon the pH of the bile.

TABLE II
Phosphate feedings

pH	Weight of Stone Grams Before	Weight of Stone Grams After	Number of Days	Amount Administered c.c.
8.73	0.016	0.016	25	100
8.88	0.019	0.018	25	100
9.07	0.020	0.020	25	100
8.93	No stones		29	145
8.80	No stones		29	145
8.83	No stones		29	145
8.86	No stones		5	45

To seven guinea pigs a four per cent hydroalcoholic solution of salicylic acid was administered orally after stones were placed in the gall bladders, in order to determine whether or not this acid would affect the bile or dissolve stones. Table III presents the data obtained in this experiment. It will be seen that no significant change has occurred in the weight of the stones or in the pH of the bile.

TABLE III
Salicylic acid feeding

pH	Weight of Stone Grams Before	Weight of Stone Grams After	pH	Number of Days	Amount Administered c.c.
	0.029	0.031	9.00	17	71.0
	0.019	0.019		17	71.0
8.91	0.028	0.027		9	26.5
9.06	0.043	0.040	8.90	5	15.0
9.14	0.018	0.016		2	6.0
8.83	0.017	0.017	8.80	9	26.5
9.03	0.032	0.033	9.01	3	6.5

A two per cent hydroalcoholic solution of glycocholic acid (C. P. Riedel de Haen, Inc.) was administered orally to four guinea pigs. This acid was found to be extremely toxic even in small doses so that it could not be given for long periods. Table IV presents the findings in this series. No significant change in the weight of the stones was noted. The pH of the bile following the administration of glycocholic acid was not obtained because insufficient or inspissated bile was present in the gall bladders.

SUMMARY

It has been shown conclusively that the acid bile of the dog's gall bladder will dissolve human cholesterol gall stones. In the present report the effect on human gall stones of an alkaline bile as is normally found in the guinea pig's gall bladder was determined. It occurred to us that since human gall stones dissolved in acid bile it was theoretically unlikely that similar dissolution would occur in alkaline bile. Our experiments have shown that gall stones do not dissolve in the guinea pig's alkaline bile even after a long period of time.

TABLE IV
Glycocholic acid

pH	Weight of Stone Grams Before	Weight of Stone Grams After	Number of Days	Amount Administered c.c.
8.91	0.024	0.020	9	28
8.88	0.053	0.053	5	17
	0.015	0.016	4	13
	0.021	0.022	2	6

The average normal pH of dog's gall bladder bile,

determined by the electrometric method is 6.85 while the average pH of the guinea pig's gall bladder bile is 8.93.

Certain substances, namely, sodium dihydrogen phosphate, salicylic acid and glycocholic acid, known to be eliminated partially by the biliary system, do not upon oral administration, influence the pH of bile. Apparently, the pH of bile, although we are fully cognizant that this is a resultant of other factors, is an important etiologic factor in the dissolution of gall stones.

Peptic Ulcer in Children: A Follow-up Study of Cases Reported Previously and a Report of Additional Cases*

By

LEON BLOCH, M.D.

and

A. M. SERBY, M.D.

CHICAGO, ILLINOIS

FOUR years ago in a paper on peptic ulcer in children (1) the authors in conjunction with I. P. Bronstein called attention to the fact that duodenal ulcers in children were relatively frequent occurrences. There were comparatively few reports of this condition in the literature. The reason for the infrequency, it was suggested, was that digestive upsets in children were not always given the attention they merited. Since the appearance of our first paper more than twenty-five additional reports on gastric and duodenal ulcers in children have appeared in print. Foshee (2) collected eighteen cases of gastric ulcer and added one more from his own experience. We have also noted that the diagnosis of peptic ulcer in children is made more frequently where previously a statement of its frequency was looked askance at. We are at this time reporting on the subsequent course of the five roentgenologically proven cases of duodenal ulcer in children previously cited and submitting the records of eight additional cases.

Case 1. B. W., female, age 9½ in 1932, complained of a more or less regularly recurring post-prandial distress for three years. Because of an urticarial rash which occurred coincidentally with vernal and autumnal recrudescenses of her distress, the symptoms were thought to be of allergic origin. However, in spite of some definitely positive responses to skin tests the patient was able to eat the very food she was apparently sensitive to without any ill effects. She now weighs 119½ lbs. and is practically free from distress. Fluoroscopic examinations at six months intervals have repeatedly confirmed the original diagnosis of duodenal ulcer although the lesion is becoming somewhat less readily recognizable.

Case 2. M. Z., female, age 11 in 1932, complained of an irregular post prandial discomfort for six months prior to coming to the clinic. There was a definitely demonstrable duodenal defect on the posterior duodenal wall. She was a professional dancer and did not watch her diet carefully. Reexamination in 1933 again showed the defect. In 1934 she was admitted to the children's division of the Michael Reese Hospital because of severe abdominal pain and placed on an ulcer regime, and became and remained free from distress until January, 1935. In September, 1935, she was operated upon for acute appendicitis and has remained free from distress up to the present time.

Case 3. N. S., male, age 13, was well until five months prior to coming to the clinic, at which time he began to complain of post-prandial distress. Two roentgenologic examinations revealed a duodenal defect. He was placed on ambulatory management and remained free from distress for three years. Because of a slight recurrence of symptoms in June, 1935, he was reexamined and the lesion was again demonstrable. He has been free from distress since then although he swerves from his diet from time to time.

Case 4. F. A., female, age 5, was seen in consultation by one of us in 1931 with Dr. W. J. Corcoran. Her gastro-intestinal complaints appeared one month previously and consisted of pain after eating. She has been lost track of and therefore no subsequent history can be given.

Case 5. The history of G. K., age 8½, dated back to ten weeks after birth when she first vomited a small amount of blood. Hematemesis occurred at intervals until she was three years old. At the age of 6 she again vomited blood and complained of substernal distress on taking food. Hematemesis occurred on and off until one month before we saw her, when a profuse hemorrhage occurred. One month later X-ray examinations failed to reveal a gastro-intestinal lesion which might account for the hemorrhages. Because the bleeding continued and a severe anemia developed, she was sent back to Dr. H. M. Richter, the referring physician, for transfusion and exploration. Two small shallow ulcers were found on the posterior duodenal wall one centimeter from the pylorus, only after an incision was made in the duodenum. Subsequent to the appearance of our report she developed increasing pain on swallowing, requiring at first direct dilatation and then retrograde dilatation with the aid of a string passed into the stomach through a gastrostomy. When the family moved to Philadelphia the child was placed in the care of Dr. Gabriel Tucker who continued the treatment. This child had multiple ulcers of years standing, involving the duodenum and the esophagus, the latter leading to stricture.

PRESENT SERIES

Case 1. J. R., female, age 11, came to the office in 1934 complaining of epigastric pain over a period of six months, coming on one-half hour after taking food and relieved by vomiting or eating. X-ray examination revealed a definite duodenal defect and duodenal stasis. She was completely relieved of her distress on ambulatory management and has remained so up to the present time.

Case 2. R. R., age 12, was first seen in 1932. He had

*From the Clinic of Gastro-enterology, The Michael Reese Hospital, Chicago (Mandel Clinic).
Submitted October 29, 1936.

had more or less post-prandial discomfort for four years, with occasional freedom from all distress. Soda bicarbonate afforded relief. A gastric analysis revealed 35 free and 58 total acid. X-ray examination demonstrated a typical duodenal defect. He was placed on ambulatory ulcer management and has been free from distress when last heard of in September, 1936. It is interesting to note that at the time the child was being examined the father was being treated for duodenal ulcer also.

Case 3. The history of S. L., male, age 11 in 1932, is that since the age of 8 months he would vomit everything he ate a short time after taking food. At times the vomiting was projectile in character. When his meals were restricted to small quantities he would vomit much less. At the age of three he developed epigastric cramps which were relieved by vomiting. During the last two years he complained of a feeling of a lump in the epigastrium, coming on fifteen minutes after a large meal or when he became hungry at school. Small amounts of bland food relieved the pain. X-ray examination revealed a definite duodenal defect. A regime of a soft comminuted diet, frequent feedings and tincture of belladonna afforded him complete relief of his symptoms. When seen three years later he was free from any distress.

Case 4. A. W., male, age 14, came to the clinic in September, 1934, stating that after eating hamburger steak or a full meal he became nauseated, belched considerably, passed much flatus, and had severe abdominal cramps. One month later he developed pain a few minutes to an hour and a half regularly after taking food.

During this period he was receiving injections of antuitrin-S in another department of the clinic for undescended testicles. X-ray examination revealed a definite duodenal defect. He obtained relief of his distress when he was placed on a diet of frequent feedings of bland comminuted food, and a powder containing fifteen grains each of calcium carbonate and soda bicardonate, and also five minims tincture of belladonna after the morning, noon and evening meals. Again it is interesting to note that 13 years previously his mother had undergone a subtotal gastric resection for duodenal ulcer.

Case 5. J. W., was 21 years old when he first presented himself in the gastro-intestinal clinic. In April, 1927, at the age of thirteen he came to the pediatric clinic stating that for ten days he had pain in the epigastrium and left lower quadrant of the abdomen. The pain appeared one hour after a meal, especially hamburger sausages, became worse after two hours, and so severe that "he was doubled up." This condition recurred in 1928, 1929 and 1933. In 1935 he began to complain of heart burn which was relieved by soda or vomiting. X-ray examination showed fasting retention and a clover leaf deformity of the duodenum. The patient refused to come back to the clinic for treatment or further observation.

Case 6. M. K., age 12, female, came to the clinic on April 3, 1935, complaining of pain in the right upper quadrant of the abdomen for one year. The pain came on two hours after taking food and occasionally awakened her from sleep. She had frequent hunger pains while at school. She had had many sore throats. X-ray examination revealed a definite duodenal defect, and tenderness on pressure over the duodenum. Relief of her symptoms was obtained on ambulatory ulcer management.

Case 7. E. M., age 12, male, came to the clinic in November, 1934, stating that for two years he had periumbilical pain after eating. The pain persisted for several hours or until he took soda. Six months later he began to vomit during the day and more frequently in the early hours of the morning. He had frequent nocturnal pain. X-ray examination revealed a definite duodenal defect. He was admitted to the hospital and placed on a diet of frequent feedings of soft, comminuted food and obtained complete relief. One year later after some dietary indiscretions he had a return of symptoms and on reexamination again showed a duodenal defect. He obtained relief on resuming the original diet. During the last year he had recurring distress every three or four months and was again admitted to the hospital. The child's father and sister had both undergone subtotal gastric resections for duodenal ulcers and another brother had post-prandial abdominal pain.

Case 8. Female, age 15, came to the clinic in 1933 stating that she had abdominal pain for seven years. It appeared in the epigastrium or both lower quadrants of the abdomen, at times was quite severe and was not definitely connected with the taking of food, or accompanied by vomiting. X-ray examination revealed a definite duodenal defect. She obtained relief on an ambulatory ulcer regime and tincture of belladonna. She was seen two years later at which time she was free from pain as long as she was careful with her diet.

In addition to the above mentioned patients is another group whose ages ranged from eighteen to thirty-nine, in whom the symptoms of ulcer appeared in childhood and continued into adulthood. *S. E.*, age 39, male, first noted his distress at the age of 16; *E. M.*, age 27, female, at the age of 12; *N. R.*, male, age 18, at 17. His sister, age twenty-four, began to have symptoms at the age of 18. The father of the last two patients had symptoms of ulcer for years, a severe hemorrhage, and was finally resected for duodenal ulcer with complete relief. In all of the above cited cases the diagnosis was confirmed roentgenologically.

COMMENT

With all the apparent frequency of duodenal ulcer in children, the incidence is still comparatively low. There is no way of telling accurately how many children, if subjected to a roentgenologic examination for minor gastric upsets, would reveal lesions. In the gastro-intestinal clinic only adults are seen and children are referred here on exceptional occasions only. From conversations with some of the staff of the pediatric clinic it would appear that such lesions are found more frequently than before. A careful inquiry into the history of the duration of the symptoms with attention focused on the period of childhood, would undoubtedly uncover a higher incidence than heretofore suspected. That has been our own personal experience since we directed our attention to that phase of the question.

A not unimportant aid in the diagnosis of ulcer is the family history. More and more have we, as well as many others, come to feel that the co-existence of ulcer in two or more members of a family is not merely a coincidence. We have encountered a family of four in whom both parents had undergone operations for ulcer and both children with active ulcers, a family of eight children with six having ulcers, a family of four with three having ulcers, in whom the symptoms began in the second decade of life. If a doubt arises as to the advisability of making a roentgenologic examination in children with mild gastro-intestinal symptoms, a family history of ulcer should be sufficient warrant to recommend it. It is difficult to make any accurate statement of the proportion of the familial to the total number of cases of ulcer; in other words, the importance of the role of heredity. In our experience it would appear to be close to twenty-five per cent. Attention to this subject was called in our previous communication.

The majority of children affected with ulcer seem

to respond readily to an ambulatory form of treatment consisting of frequent feedings of well comminuted bland foods, with occasionally some calcium carbonate or soda and tincture of belladonna three times daily. The outstanding exception was G. K. in the first series whose duodenal lesion bled profusely and was associated with an esophageal one which terminated with stricture formation. The relapses in most cases were due to dietary indiscretions and were readily controlled by a resumption of the proper diet. The one patient with obstructive symptoms was 13 years old when he first appeared at the clinic and 21 when we saw him. He may require surgical attention. It would be interesting to be able to follow up the others to see whether any complications arise that might make surgical attention necessary when adulthood is reached. However, none of the four patients cited in whom the lesions began in childhood or adolescence have so far developed any evidences of obstruction or failed to respond to medical management.

CONCLUSIONS

1. The subsequent course of four of five previously reported cases of duodenal ulcer in children is reviewed.

2. Eight new case reports are submitted.

3. Attention is directed towards the importance of the family history in the diagnosis of duodenal ulcer.

4. Ambulatory management seems to suffice in nearly every patient and complications are comparatively rare.

Colon Motility: An Experimental Study of the Colon in the Dog*

By

ALEXANDER SLIVE, M.S., M.D.

and

SAMUEL J. FOGELSON, M.S., M.D.

CHICAGO, ILLINOIS

THIS investigation was stimulated by our unsatisfactory clinical results in the treatment of the so-called "spastic colitis" in the human. Colon motility in man has been for practical purposes limited to fluoroscopic observations. We may conclude that the bowel content appears to be "pushed along" without the aid of peristaltic waves but at irregular and variable times there may occur "mass movements" as described by Hurst (6). The literature on colon motility in the dog was found to be not only extremely sparse but also contradictory in nature. This investigation included a study of motility in the normal colon, the changes of motility in the colon inflamed by chemical irritation, and the effects of drugs commonly used upon the function of irritated bowel.

METHODS

Thiry fistulae in the colons of dogs were made in the following places: 1—adjacent to the cecum, 2—the ascending colon and 3—the transverse colon. The recto-sigmoid as a site for colon fistulae was abandoned because none of our animals survived the surgical procedure.

1. The motility of the isolated bowel segment was studied in the customary fashion by inserting a balloon connected to a water manometer. Bowel contractions were recorded on a revolving kymograph. For the establishment of the normal types of contraction an air filled balloon was used. In the pathologic experiments a water system was used.

2. The gastro-colic reflex was studied in normal dogs which were starved for twenty-four hours. Peristaltic activity of the fistulae was then recorded after which a meal of milk, eggs and syrup was given to the animals. In one series this meal was put into the stomach by tube, and in the other series was ingested normally. In both instances the peristalsis of the fistulae were studied after feeding.

3. While the activity of the fistula was being recorded the dogs were injected subcutaneously with the drugs to be evaluated in order to determine their effect upon colon motility.

4. Inflammatory changes were made in the fistulae by irrigation with mustard oil in an olive oil vehicle. When this was done three times weekly for three to four weeks a pronounced inflammatory colitis resulted. The type of motility of such an inflamed bowel was studied during the activity as well as the regression of the pathologic processes. In addition the effect of atropine sulphate gr. 1/60 upon such an irritated colon was also investigated.

RESULTS

I. Normal Colon Studies. A—In the colon adjacent to the cecum, 425 minutes of recording revealed active peristalsis for 360 minutes. The average duration of a period of peristalsis was 25 minutes, followed by an inactive interval of 5 minutes. The contractions were quite rhythmic, having a rate of 2-3 per minute and an altitude of 18 mm. water. The waves, (Fig. 1-A and B) were peaked, ascending and descending sharply.

B—In the ascending colon 420 minutes of recording showed peristalsis for 300 minutes. The duration of the active periods averaged 22 minutes and the inactive interval 10 minutes. Two varieties of contractions were observed here. The first, type 1, (Fig. 1-C) were rapid, 2-3 per minute, while their amplitude was small, 4-6 mm. of water. The waves were very regular and rounded. The type 2 contractions (Fig. 1-D) were slower, 1 per minute, with an amplitude of 12 mm. water. These contractions were not as regular as the first type and the crest of the waves were flatter, indicating a sustained contraction.

*From the Department of Surgery, Northwestern University Medical School, Chicago, Illinois.
Submitted October 28, 1936.

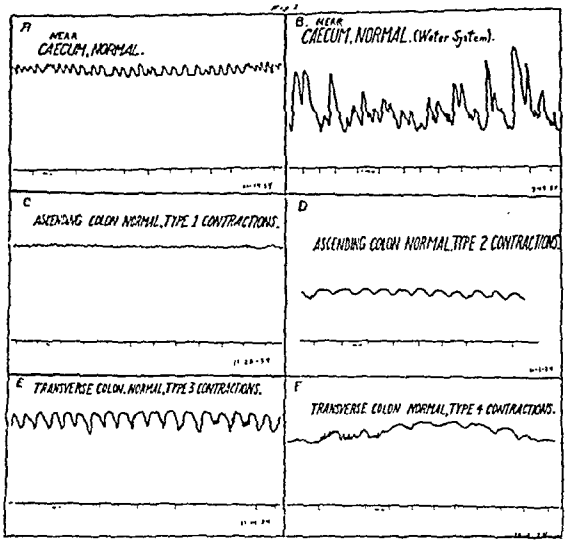

Fig. 1

C—In the transverse colon 375 minutes of recording demonstrated peristalsis for 265 minutes. The duration of peristaltic activity averaged 18 minutes and the rest interval 9 minutes. Two types of contractions were also observed in this region. In the first, type 3, (Fig. 1-E) the rate was slow, 1 per minute, and the amplitude very large, measuring 26 mm. water. The waves were rhythmic, and although the crests were flat, ascent and descent was abrupt. The type 4 wave (Fig. 1-F) was more of a tonus change with irregular, small waves superimposed on the main one. The height of this contraction at its peak was 26 mm. water.

D — Gastro-colic reflex — Meals given by stomach tube neither initiated nor augmented peristalsis in the Thiry fistulae of the cecal area, ascending colon, or transverse colon. When, however, the same type of meals were given by mouth, a marked increase in the rate of peristalsis was seen in the colon adjacent to the cecum within 2 minutes, and longer, sustained contractions were initiated in the transverse colon.

II. Effect of Drugs. Results had to be cautiously evaluated and well controlled because spontaneous periods of initiation and inhibition of peristalsis occurred. Atropine sulphate gr. 1/60, caused complete protracted inhibition of all peristaltic activity in from 9 to 15 minutes (Fig. 2-A). This drug had the same effect when given after pilocarpine. Neither initiation, augmentation, nor inhibition of peristalsis was observed when the following drugs were used: epinephrine 0.3 c.c., insulin 3 units, histamine 1 mg., pilocarpine 6 mg., pituitrin (surgical and obstetrical) 0.5 c.c., morphine sulphate gr. ¼, 1-histidine monohydrochloride (Larostidin) 3 c.c., and phosphate salt of 3-diethylamino-2 2-dimethylpropanol tropic acid ester, (Syntropan) 0.02 gm.

III. Colon Motility and Mechanical Small Bowel Ileus. Eight weeks post-operatively one of the colon Thiry fistula animals was listless and losing weight. Recordings of motility in the fistula at this time demonstrated that the contractions had increased in amplitude from 12 mm. to 44 mm., and the rate decreased from 2.7 to 1.6 per minute, (contrast A and B, Fig. 3). The abnormal contractions persisted until the animal died one month later, when post-mortem examination revealed a mechanical (adhesive band) obstruction of the ileum, with gangrene, perforation and peritonitis.

IV. Experimental Colitis. The acute chemical colitis in a colon Thiry fistula secondary to mustard oil irritation caused an immediate and markedly elevated contraction which persisted for about 2 minutes (Fig. 4-A). Tracings taken after 4 weeks of mustard oil irrigations demonstrated a persistent, increased tonus with contractions whose rate and amplitude were much diminished (Fig. 4-B). Atropine sulphate gr. 1/60 injected into such an animal caused complete cessation of peristalsis and a marked decrease of tonus within 20 minutes (Fig. 2-B). Three weeks after mustard oil irrigations were stopped a tracing of the convalescent colon fistula showed a increase in the rate and amplitude of the contractions, but decrease of tonus (Fig. 4-C). Two weeks later a tracing demonstrated almost complete recovery (Fig. 4-D).

DISCUSSION

Bargen and Larsen (3) and Plant and Miller (8), using balloons in dog colon fistulae reported, respectively, contraction rates of 8 to 10 and 7 to 14 per minute. Three types of contractions were described by Templeton and Lawson (9). These were rapid contractions appearing as a simple curve, slower contractions surmounted by the first type, and tone changes surmounted by both of the preceding. Welch and Plant (10), reported that the muscular activity, of the dog's colon was very irregular, consisting chiefly of marked variations of tonus, with or without superimposed contractions. Our tracings (Fig. 1) demonstrate marked rhythm and rates of peristalsis varying from 1 to 3 per minute, whereas tonus waves surmounted by smaller waves were infrequently seen and then only in the transverse colon.

Our studies indicate that the motility of the colon decreases in an analward direction, confirming at least part of Alvarez's theory (2) of intestinal gradients. In the vicinity of the cecum the greatest activity was observed, the contractions all being rhythmic, peaked and frequent. The tandem balloon studies of Templeton and Lawson (9) reveal that the early part of the period of activity in the proximal colon was accompanied by a delay of contractions analward, while the latter part of the period showing contractions delayed oralward and increased analward. If the dog's colon is physiologically a distal colon, and this is the opinion of many investigators, differentiation of propulsive and nonpropulsive activity becomes a minor consideration because the organ should have

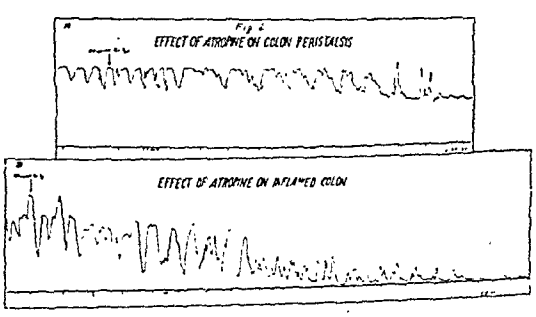

Fig. 2

no need for nonpropulsive movements. Our results show greatest activity nearer the cecum and diminution of activity analward, suggesting that the dog's colon is not a simple distal colon. There is a similarity to the herbivorous animal wherein the area near the cecum shows the greatest activity. This might very well indicate a churning or nonpropulsive activity in the cecal region with the remainder of the organ having as its role, coordinated peristalsis for driving bowel contents toward the anus.

We agree with Welch and Plant (10), in calling the gastrocolic reflex a misnomer. It is really a feeding or appetite reflex. In our studies it produced an increase in the rate of motility near the cecum, but in the remainder of the colon only a prolongation of the individual contractions. This again suggests that the dog's colon does have differentiation of activity in its various components and therefore is not simply a distal colon. We did not experiment with the terminal colon which Templeton and Lawson (9), and Bargen and Larson (3) found almost devoid of activity.

The power of atropine to depress colon motility, even after pilocarpine administration is in accord with the work of Katsch (7), and Hirz (5). This marked inhibitory effect of atropine on the experimentally inflamed fistulae indicates the rationale of its use in humans. We cannot explain why histamine had no effect on the motility of the Thiry fistulae nor why pilocarpine, pituitrin, morphine sulphate, 1-histidine monohydrochloride (Larostidin) or phosphate salt of 3-diethylamino-2 2-dimethylpropanol tropic acid ester (Syntropan) gave no demonstrable results. Our negative experimental findings explain the futility of expecting good clinical results when using these drugs for symptomatic relief.

Alvarez (1) noticed that the injection of turpentine into the iliocecal area caused a diarrhea and rapidly emptying colon. He stated that irritation at any point in the bowel tends to slow the progress of material moving away from it. This theory (Alvarez's Law) would explain the increased colon motility accompanying small bowel ileus. We are inclined to believe that the mechanism is probably an intrinsic bowel reflex rather than a central one.

Alvarez (2) has reported that inflammation of intestinal strips doubled the normal contraction rate. The colon fistulae studied by us did not show this effect. Our graphic demonstration of motility during the production and involution of colitis indicated that an acute irritation simply produced a marked, sustained contraction which relaxed in a few minutes. The chronically inflamed colon was persistently spastic with increased tonus and irregular contractions of small amplitude and insignificant rate change. This finding simulated that of chronic colitis of man,

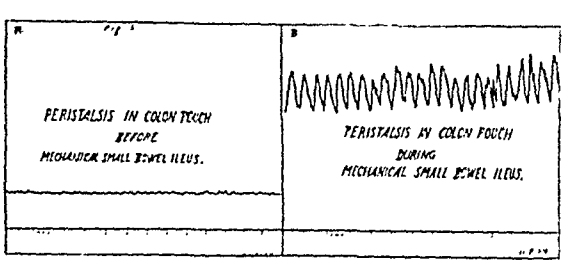

Fig. 3

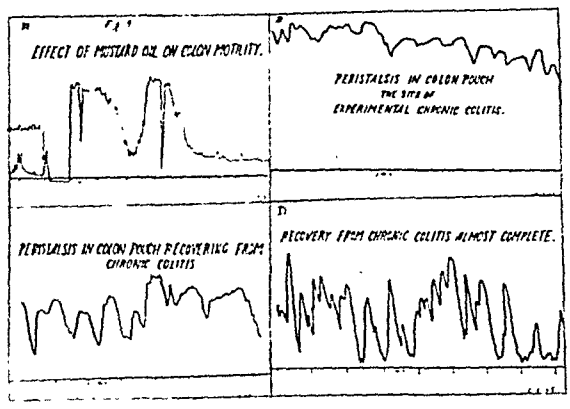

Fig. 4

where the sigmoid is felt to be persistently hard and spastic. Perhaps in man also the contractions are of small amplitude and arhythmic and therefore ineffectual for bowel content propulsion. The tracings showed that the involution of the colitis was characterized by decreased tonus, and waves of increasing amplitude and regularity.

SUMMARY

1. The motor activity of the dog's colon is characterized by rhythmic peristaltic waves, the rate of which vary from 1 to 4 per minute, decreasing in an analward direction. Near the cecum, the contractions are abrupt and of short duration, whereas analward they are less frequent and much more prolonged. Evidence points to differentiation of motility in various parts of the dog's colon, with a marked similarity to the activity of the colon of herbivorous animals.

2. There is no gastro-colic reflex. There is a feeding or appetite reflex to the colon which causes an increase in the rate of contractions near the cecum and marked prolongation of peristaltic waves distally.

3. Atropine sulphate will completely inhibit the activity of a normal or inflamed colon. Histamine, pilocarpine, insulin, pituitrin, morphine, Larostidin and Syntropan were found by us to be without demonstrable effect on the motility of the colon.

4. In one animal mechanical ileus in the small bowel caused a marked increase in the motility of the large bowel.

5. A chemical irritation of the colon caused a spastic contraction which relaxed after a few minutes. Peristalsis in a chronically inflamed colon is characterized by increased tonus and irregular, feeble contractions. With healing of the inflamed colon abnormal peristalsis slowly disappeared and function again became normal.

The Value of Histidine in Prevention of Experimental Ulcer in Dogs*

By

DAVID J. SANDWEISS, M.D.
HARRY C. SALTZSTEIN, M.D.
and
WALTER S. GLAZER, M.D.
DETROIT, MICHIGAN

AS is well known, the Mann-Williamson operation of surgical duodenal drainage produces peptic ulcer in almost 100% of dogs (1). Weiss and Aron (2), in 1933, reported that histidine injected daily prevented this development of ulcer. They performed the Mann-Williamson operation on five dogs. Two, used as controls, developed ulcer. Three were given daily injections of histidine-tryptophan starting immediately after the operation. These three animals were sacrificed five, six, and ten weeks, respectively, postoperatively. No ulcers were found in any of these three animals. As a result of further experimentation (not on Mann-Williamson dogs) they concluded that histidine alone had a protective value against ulcers. Postulating that histidine prevented ulcer, they began treating ulcer patients by injections of this substance intramuscularly. There have appeared, since their report, approximately 100 clinical papers (3) generally favorable to the effect of histidine upon the treatment of peptic ulcer in man. The more important ones were summarized by Kirby Martin (4), and by Sandweiss (5).

Recently Flood and Mullins (6) repeated Weiss and Aron's work (which up to this time had been the sole experimental basis for this extensive clinical literature). They used 17 dogs: five were kept as controls and the remaining 12 were injected with daily doses of varying amounts of histidine (Larostidin. Dosage: 4.8 to 10.9 mg. of histidine per kilogram body weight). The five controls developed ulcer in from 51 to 104 days, four of them with perforation, one a shallow ulcer. Of the 12 dogs receiving histidine, five died without evidence of ulcer in from 40 to 82 days. Six showed ulcers, either large, perforated, or multiple, dying in from 51 to 94 days. The remaining animal died of intestinal obstruction on the 56th day, and showed a small superficial erosion of the first portion of the jejunum. Thus 45% of the animals receiving histidine failed to develop ulcers.

We have recently also repeated these experiments. Our method was as follows:

EXPERIMENTAL

The standard Mann-Williamson operation was done. The pylorus was sectioned and the distal end was inverted. The jejunum was divided about 10 cm. beyond the ligament of Treitz. Anastomosis between the stomach and the distal end of the jejunum was then done, generally end to side, though occasionally end to end. The lower anastomosis between the proximal jejunum and terminal ileum was always end to side, and about 20 to 30 cm. from the ileo-cecal valve. Fine silk was used throughout, with no clamps. The dogs were starved 24-48 hours before operation. Ether anaesthesia was used. They were given water as tolerated for four days postoperatively (plus saline subcutaneously as needed, 3-4 days) and then placed on a diet consisting of finely chopped hamburger, bread and milk. The reason for this was to allow no roughage.

Histidine (Larostidin) injections were given twice daily, in the same amount (1 c.c.) to each animal.* The injections were started either before or within a few days after the operation, as indicated on the table. Fourteen dogs received histidine. Twelve received none, and were used as controls.

TABLE I

Histidine treated dogs

Dog	P.O. Duration of life (days)	Histidine started (days of OR)	Results
1	29	4 days P.O.	Small ulcer with low grade inflammatory reaction at base.
2	10	2 days P.O.	Crescent shaped ulcer with inflammatory changes.
3	195	5 days P.O.	Perforated ulcer.
4	55	1 day before OR	Perforated ulcer.
5	43	day of OR	Perforated ulcer.
6	19	day of OR	Death from Distemper. However, there was marked localized jejunitis with edema and clubbing of villi and inflammatory infiltration of wall. Early ulcer.
7	45	5 days P.O.	Perforated ulcer.
8	121	2 days P.O.	Small superficial ulcer.
9	83	3 days P.O.	Perforated ulcer.
10	277	1 day P.O.	Perforated ulcer.
11	33	2 days P.O.	Death from intussusception. *No* ulcer.
12	101	day of OR	Perforated ulcer.
13	16	day of OR	Perforated ulcer.
14	58	1 day P.O.	Profuse hemorrhage—small punched out ulcer.

RESULTS

Of twelve controls, all died with ulcers.

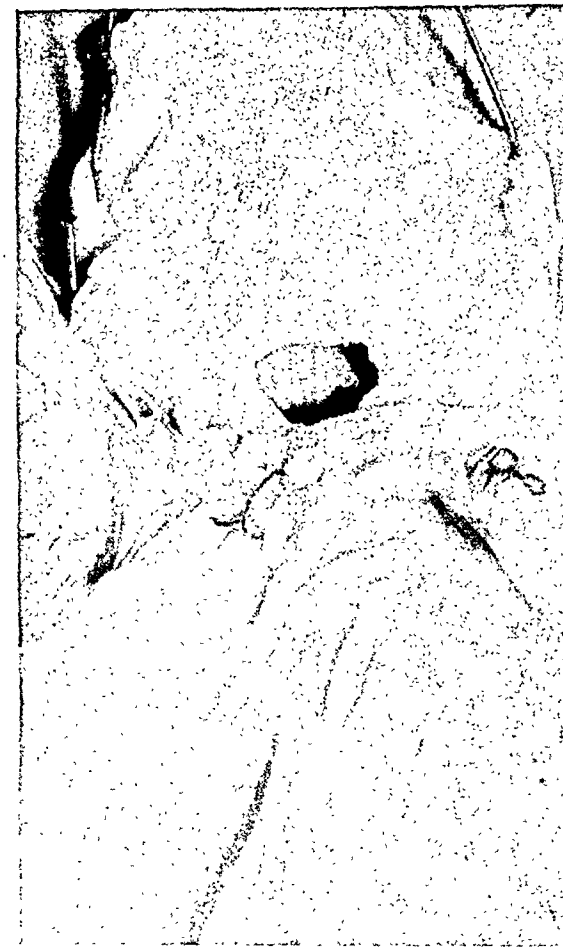
Of fourteen dogs, receiving histidine, eight died of peritonitis following perforation of jejunal ulcers.

*Two c.c. of Larostidin daily, representing 80 mgm. of histidine was given per day to each dog. The average weight of the animals was 7-16 Kilo. (15-35 lbs.) and this dosage was therefore approximately 2 to 3 times the dose per Kgm. body weight suggested and used in the treatment of patients with peptic ulcer. Part of the Larostidin was furnished through the courtesy of Hoffmann-La-Roche Co.

*From the Laboratory of Experimental Surgery, Harper Hospital, Detroit, Mich. Aided by a grant from the Mendelsohn Fund.
Submitted December 11, 1936.

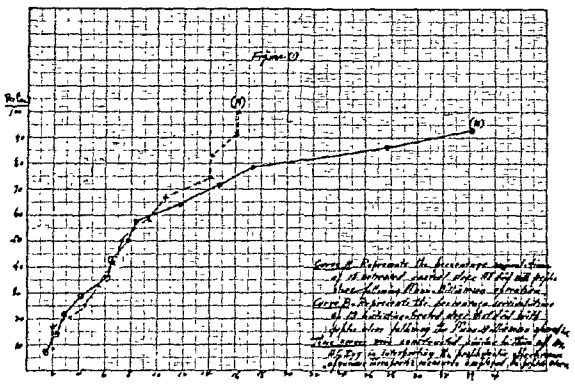
Dog No. 12 died 101 days post-operatively. 2 c.c. of histidine monohydrochloride (Larostidin) were injected daily beginning with the day of operation to the day of death. Perforated ulcer.

Another had profuse hemorrhage from a small deep ulcer. Another, dying on the 121st day, showed a superficial ulcer. With one exception, these 10 animals *lived more than 40 days after the operation.* Two dogs died 10 and 30 days post-operatively and showed small ulcers with low grade inflammatory reaction at bases. One died 19 days post-operatively showing marked localized jejunitis with edema and clubbing of villi and inflammatory infiltration of wall considered as an early ulcer. Only one died (on the 33rd day) without ulcer formation. Autopsy revealed intussusception as the cause of death. We believe that this dog would also have developed an ulcer had intussusception not developed, and death ensued.



Thus, 13 or 93% of histidine treated animals showed ulcer formation. If they lived longer than one month, they had typical chronic perforating ulcers. If they died within the first month, they showed small ulcers with inflammatory reaction at bases (two) or localized jejunitis (one). One dog died 16 days post-operatively from a perforated ulcer. All of these lesions were just distal to the line of union between stomach and jejunum. They did not involve the line of anastomosis and never began more than one cm. distant from this line, and they showed little tendency to fibrosis and repair. There was no gross or microscopic difference between the ulcers in control and treated animals.

It should be noted (Fig. 1) that, whereas all of the twelve control dogs that died of ulcer, died within 16 weeks, post-operatively, only ten of our thirteen histidine treated dogs died with ulcer within the same period of time. The remaining three histidine treated dogs that died with ulcer, died later than the maximum survival of the control dogs. (One died 17 weeks, post-operatively; one, 28 weeks post-operatively and the third, 39 weeks after the operation). It may therefore be said that although histidine neither prevented ulcer formation nor healed the ulcers after they had formed, three histidine treated dogs lived longer than the control dogs, although they all subsequently died with ulcer. In our opinion there is no significant difference between the curves of treated dogs and controls—which we believe would be the opinion of those who have had extensive experience in Mann-Williamson dogs.



EXPERIMENTAL WORK OTHER THAN ORIGINAL WEISS-ARON EXPERIMENT

Fontes and Bauer (8) repeated the experimental work of Weiss and Aron but instead of daily intramuscular injections of histidine gave histidine orally in doses of from 0.25 to 0.5 gm. daily to 100 dogs. They report that 30% of their dogs did not develop ulcer. These authors, however, question histidine as being the sole factor in the non-appearance of experimental ulcer.

Recently Stalker (12) of the Mayo Foundation has tried the protective effect of various substances on experimental ulcers in dogs, produced by cincophen. All control animals developed a chronic ulcer within 30 days. The dogs treated

Dog No. 13 died 16 days post-operatively. 2 c.c. of histidine monohydrochloride (Larostidin) were injected daily beginning with the day of operation to the day of death. Perforated ulcer.

by standard diet alkaline regime developed no chronic ulcer. Those on milk developed only a superficial ulcer. Mucin protected 50% from the development of a chronic ulcer. "Every dog treated with Larostidin developed a chronic ulcer."

Volini and McLaughlin (9) produced gastric ulcers in rats by repeated injections of histamine dihydrochloride as well as by the use of repeated histamine enemata. They report that these experimental ulcers did not occur when the animals were protected by previous injections of histidine monhydrochloride. However, Matzner and Windwer (10) were unable to prevent with histidine injections, experimental gastric ulcers in rats produced by their pepsin-hydrochloric acid method (11). On the contrary, by injecting histidine daily into otherwise normal rats, using no ulcer producing agent, 50% developed ulcer. They suggest that histidine may be converted into histamine by simple decarboxylation and thus produce ulcer (histamine is a well known ulcer producing agent).

THE HISTIDINE DEFICIENCY THEORY OF PEPTIC ULCER

Weiss and Aron assumed that peptic ulcer was the result of a deficiency or absence of the amino acid, histidine.

Martin (4) points out that histidine is a constitutent of most of the simple proteins and may be obtained from a great variety of foodstuffs, most important of which are beef, eggs, fish and milk. He says: "there is no convincing evidence from feeding experiments that a deficiency of this substance (histidine) can be produced in animals." Mitchell and Hamilton (7) state that the presence of histidine in foodstuffs is so universal that the exclusion of histidine-producing foods would make a diet incomplete in other indispensable dietary factors.

Flood and Mullins (6) in repeating the experimental work of Weiss and Aron investigated a variety of factors in blood chemistry, local chemistry and pathology, following surgical duodenal drainage, to see whether there was any difference between controls and histidine treated animals. They found marked decrease in serum protein and bicarbonate with an accompanying rise in serum chloride following surgical duodenal drainage. Blood amino nitrogen shows wide fluctuations and some tendency to decrease. There is no tendency to an increase in gastric HCl concentration following operation. There is, in fact, late subacidity. All animals showed progressive secondary anemia. All of these changes were exactly parallel in both control and treated series. In addition, the local amino nitrogen content of the jejunal and antral portions of the stomach were determined, since it had been claimed that histidine might exercise a protective effect against jejunal ulcer by some mechanism involving local increase in tissue amino nitrogen. There was no significant difference between the two groups.

Flood and Mullins further report that pathologically, there was no evidence of gastritis. There were frequent submucosal hemorrhages in the small intestine and colon, and "at times the villi of the upper jejunum appeared shrunken and the surface of the intestine has lost its normal velvity appearance." There was no evidence of fibrosis in the wall of the jejunum beyond a short distance beyond the bed of the ulcer. These changes were identical in both groups, except that "atrophy of the jejunal mucosa was less marked in some of the dogs receiving histidine than in the controls." Thus, although 45% of the animals treated with histidine failed to develop ulcer, no substantiation of the amino acid deficiency theory of histidine action was obtained.

The difference between our results and those of Flood and Mullins may possibly be explained by the fact that in their experiments, the duodenum was divided at a point about one cm. beyond the pylorus. In the original Mann-Williamson operation as well as in our experimental work, the section was made directly at the pylorus. The possible protective mechanism of the duodenal mucosa was thus entirely eliminated. Ivy and Fauley (13) reported that in three of a series of 11 Mann-Williamson dogs, no ulcers were found when the duodenum was sectioned leaving a small stump attached to the pylorus. The small stump of the duodenum which Flood and Mullins left attached to the stomach may account for the 45% protection against ulcer in their dogs.

It appears that there is no experimental evidence that a deficiency or absence of histidine is the cause of peptic ulcer. Recent clinical reports substantiate the above experimental work. Kirby Martin (4) states that when symptom-free intervals result "the clinical improvement succeeding histidine-hydrochloride therapy in acute peptic ulcer appears to be symptomatic and transient." Sandweiss (14) states that

TABLE II
Control dogs

Dog	P.O. Duration of life (days)	Results
15	31	Perforated ulcer.
16	113	Perforated ulcer.
17	51	Perforated ulcer.
18	66	Three ulcers.
19	38	Circular ulcer 1 cm. extending into muscularis.
20	13	Perforated ulcer.
21	46	Large ulcer.
22	98	Perforated ulcer.
23	74	Perforated ulcer.
24	99	Perforated ulcer.
25	113	Perforated ulcer.
26	13	Perforated ulcer.

results obtained with injections of distilled water compare favorably with those of histidine, reporting that in a series of 22 patients treated with daily injections of distilled water, 13 became symptom free. Flood and Mullins (15) report similar good results in

8 of 12 patients treated with daily injections of saline.

SUMMARY

We are unable to corroborate the original experimental work of Weiss and Aron, that histidine has a protective value against peptic ulcer produced in dogs by the Exalto-Mann-Williamson operation. Of fourteen dogs receiving daily injections of histidine, following surgical duodenal drainage, (2 c.c. Larostidin daily which contains 80 mgm. of histidine) 13 or 93% showed ulcer formation. Of 12 controls, all developed ulcers.

The histidine deficiency theory of peptic ulcer is discussed. There is no evidence that a deficiency or absence of histidine is the cause of peptic ulcer.

Note: The authors are indebted to Dr. A. C. Ivy for his valuable advice in this work; also to Dr. Plinn F. Morse, Pathologist, Harper Hospital, Detroit, Michigan, for the gross and microscopic examinations of the specimens obtained at autopsy. Mr. I. Silver assisted in this work.

Experimental Production of Polyposis of the Colon in Rats*

By

FREDERICK HOELZEL

and

ESTHER DA COSTA, M.S.

CHICAGO, ILLINOIS

IN attempting to produce duodenal ulcers in rats by dietary means, we tried feeding a mixture of 200 (parts by weight) pulverized cellulose, 43 casein, 43 corn starch, 5 dry yeast powder, 5 alfalfa meal and 4 salt mixture. This diet was intended to supply a large amount of roughage, a relatively high proportion of protein and practically no fat. Sixteen days after eight rats were placed on this diet one rat (Rat 740) died. Upon autopsy, numerous ulcers were found in the prostomach. The main stomach was slightly eroded. The duodenum was normal. A few lesions were found in the small intestine and cecum, and inflammed areas, small papilli and larger sessile polyps were found in the colon (Fig. 1). The largest polyp (Fig. 2) snugly filled a sharp and relatively deep depression in the side of a compact fecal pellet, which consisted mainly of pulverized cellulose. The polyp served to anchor the pellet firmly and the combination apparently formed an intestinal obstruction which led to the death of the animal. The feces showed that this rat had eaten some of the above diet but the ulceration of the prostomach and a decline in weight from 306 gm. at the beginning to 169 gm. at death indicated that this rat practically starved to death (1).

Before Rat 740 was autopsied, we autopsied 716 other rats. These rats were fed a wide variety of diets which were primarily used to produce lesions in the upper part of the digestive tract (1). However, we found small papilli (one or more) in the colon of 17 of these rats and the polypoid nature of these papilli became clear when the colon of Rat 740 was observed. The colonic papilli occurred as follows among the 716 rats: Eight cases among 88 rats fed diets including a slightly fibrous type of cellulose flour; 6 cases among 40 rats fed diets including ground bran; 1 case among 123 rats fed diets with coarse bran; 1 among 14 rats fed diets with sawdust; 1 among 6 rats fed a diet without roughage but deficient in vitamin B, and none among 445 rats that were either starved, fed diets without roughage or diets including vegetables, agar, India gum or mineral oil. This distribution of polypoid lesions made it evident that the polyposis in Rat 740 was mainly due to the pulverized cellulose included in the diet and it also suggested that pulverized inert materials in general might cause polyposis. Besides this, our data suggested that the relatively high protein content of the

Submitted November 28, 1936.

diet fed to Rat 740 was another factor in the production of severe polyposis in that case.

In order to study the mechanism of polyp production more closely, 281 additional rats were fed diets including from 5 to over 95% inert materials, such as kaolin, pulverized cellulose, barium sulphate, talcum powder and flaked cellulose (ground artificial straw). The protein content of these diets varied from 18 to over 80% (of the total nutritive ingredients) and cod liver oil was often used in place of the alfalfa meal which was used in the diet fed to Rat 740. The diets were fed for periods ranging from 2 days to over 6 months. In addition to this, some of the diets were fed to 36 mice for comparison with the results obtained on rats.

The autopsies of the 281 rats showed that polyposis of the colon occurred as follows: In 36 (37%) of 96 rats fed kaolin; in 40 (33%) of 122 rats fed powdered cellulose; in 9 (31%) of 29 rats fed barium sulphate; in 1 of 3 rats fed talcum powder; in 3 of 7 rats fed granular cellulose (cellophane ground in a hammer mill); in 1 rat that was previously fed barium sulphate among 10 rats fed flaked cellulose (artificial straw cut up in a meat chopper); and in 2 rats among 13 fed kaolin plus sand. Nine rats of the kaolin plus sand group died as a result of the irritating effects of the sand. Talcum powder caused diarrhea in some rats. Seven of the younger rats on barium sulphate also developed diarrhea and showed toxic symptoms. Bismuth subnitrate could not even be used as an inert material because it proved to be highly toxic to the rats; it was evidently acted on by the acid in the stomach.

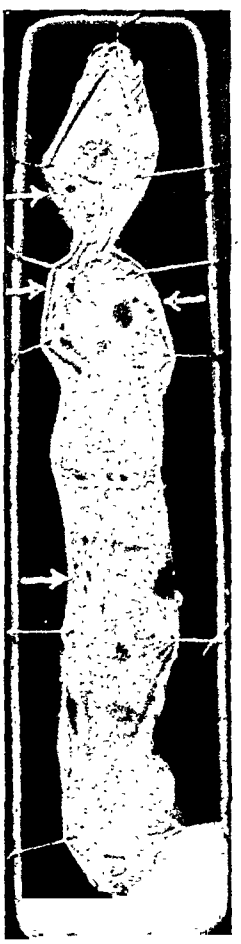

Fig. 1. Showing inflammed areas, small papilli and larger polyps in colon of rat fed a diet including 67% pulverized cellulose—16 days.

The degree of polyposis ranged from a single small papilla to two or more larger sessile polyps (Fig. 3) and one case of a pedunculated polyp (Fig. 4). The pedunculated polyp was found in the rectum of a rat (*Rat 810*) that was fed for 29 days with diets consisting of 50 (parts by weight) casein, 30 corn starch, 5 corn oil, 5 cod liver oil, 6 dry yeast powder, 4 salt mixture and either 200 kaolin or 80 kaolin, 80 barium sulphate and 40 pulverized cellulose. In some rats, polypoid lesions were found in the terminal ileum and/or cecum (Fig. 3). Polyps also developed in some rats that were not yet weaned. These rats licked or sucked up a dry mixture containing kaolin that was sprinkled in the nests for this purpose. The youngest rat with colonic polyposis (marked) was 14 days old and was exposed to kaolin only 48 hours. The greatest degrees of polyposis occurred when the diets contained from 60 to 75% pulverized inert material (from 150 to 300 parts inert material to 100 parts nutritive ingredients) but some polyposis was observed in rats fed as little as 8% pulverized inert material. A protein content of from 30 to 50% of the nutritive ingredients in the diet also seemed to be best for polyp production.

The pulverized inert materials were found to have a striking effect upon the form of the feces and this suggested their rôle in the development of polyps. Figure 5 shows fecal pellets passed by rats fed various inert materials. As indicated, the pellets produced by feeding pulverized materials often contained sharp depressions, pits or gas-pockets while flake-like materials (as well as fibrous materials, vegetables and agar) usually gave rise to fecal pellets without such pits or with only shallow depressions. The pits or depressions in the pellets frequently contained blood and pellets with blood-stained pits were passed at some time or other by about 90% of the rats fed pulverized inert materials. In fact, the only exceptions seemed to be rats with a diseased cecum and/or an irritable colon in which abnormally large amounts of mucus were secreted. Pellets with blood-stained pits were passed as early as four hours after some hungry rats were placed on a diet including kaolin. Sometimes as many as six small pits in a single pellet would contain blood but many pits contained no blood.

Observations were made, after laparotomy, on the colon of some rats with pitted fecal pellets *in situ* and this showed that bleeding into pits was due to suction of the colon into the pits and small deep pits caused suction more often than large shallow pits. The first impression usually was that the colon was perforated at such sites but closer examination always proved that the colon was only sharply drawn into the pits. The pits that did not become blood-stained were generally well filled out with gas and did not cause any suction on, or distortion of, the colon. It therefore seems that all of the pits represent gas-pockets or sites in which gas was trapped while the pellets were in process of becoming permanently formed, dehydrated

Fig. 2. Section of one of the sessile polyps shown in *Fig.* 1.

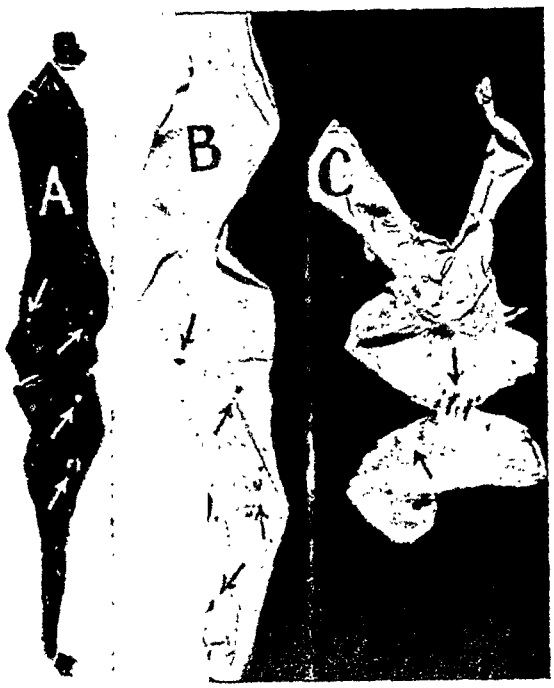

Fig. 3. Showing colonic and cecal polyposis in rats fed diets including (A) 67% barium sulphate—18 days, (B) 75% kaolin—15 days and (C) 75% barium sulphate—5 days.

or "set"—like plaster of Paris. When the gas either escaped, was pushed out of the pits or was adsorbed by the dehydrating pulverized material, the wall of the intestine was drawn in and inflammation and bleeding occurred. It was observed that the empty or suction-creating pits generally left inflammed streaks in the colon which marked their course of passage. Sometimes, more highly inflammed spots appeared along these streaks and indicated where such pits (pellets containing them) halted for longer periods. Mucosal bleeding was thus often occasioned without the development of polyps. The blood evidently helped to fill out the pits, reduced the suction and released the mucosa. Polyps were apparently formed when prolonged or intense suction led to more marked mucosal distortion and submucosal bleeding. Submucosal accumulations of blood evidently helped to keep the mucosa raised like a blood blister. Variations in susceptibility to mucosal distortion and submucosal bleeding may also explain why some rats seemed to develop polyps more easily than others. The pedunculated polyp was very likely the result of repeated peristaltic traction on a well formed sessile polyp. The larger polyps tended to cause intestinal obstruction. Small polyps or papilli and inflammed areas or streaks apparently healed rapidly and many rats were found to have rough or leathery sites in the colon which were probably sites of repeated bleeding and/or polyposis.

Our observations on mice were carried only far enough to satisfy us that the results were similar to, but, in our short experiments, less striking than the results obtained on rats. A few tests were made on guinea-pigs and rabbits but the diets which were tried caused diarrhea after being used a few days. However, the senior author of the present paper also tried various inert materials and felt that the results obtained on rats at least explained why pulverized materials in general proved to be highly unsatisfactory when used alone as a source of bulk in the diet.

Long, Kolmer and Swalm, who already repeated some of our rat feeding experiments (2), intimated that we believed that pulverized inert materials cause polyposis by inducing intestinal stasis but this does not quite represent our view. Pulverized inert materials indeed tend to cause more or less constipation, even in

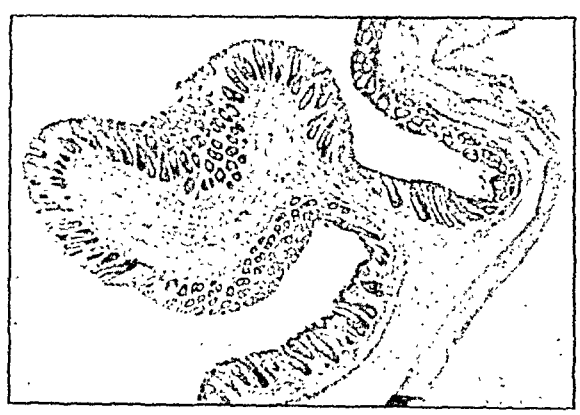

Fig. 4. Section of pedunculated polyp found in rectum of a rat fed a diet including 67% pulverized inert material (mainly kaolin)—29 days.

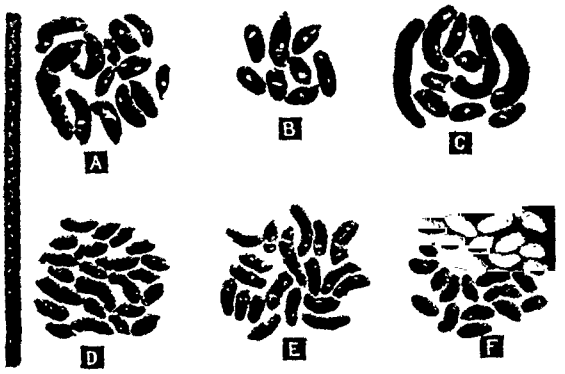

Fig. 5. Types of fecal pellets passed by rats fed diets including from 50 to 80% inert material in the form of (A) kaolin, (B) kaolin plus India gum, (C) barium sulphate, (D) pulverized cellulose, (E) powdered cellulose acetate and (F) flaked cellulose.

rats, by giving rise to relatively hard fecal pellets. The difficulty of passing such pellets was often indicated by the fact that well formed pellets (without pits) were often blood-stained at the posterior end—the end passing last. The bleeding was evidently occasioned by the great effort required to pass such pellets. However, the type of stasis which we believe was often an important factor in the development of polyposis in our rats was a more acute stasis which was mainly due to a decreased food intake. For instance, a few days after Rat 740 was placed on the polyp-producing diet (May 31, 1931) the weather suddenly became extremely hot. As a result, Rat 740 and many other rats ate practically nothing for a day or two. An acute stasis of pellets with accidentally suitable pits evidently then occurred in Rat 740 and the process leading to polyp formation was able to operate without interruption until some degree of intestinal obstruction was produced.

Later, we tried to repeat the conditions that seemed to cause the marked development of polyps in Rat 740 by transfering other rats from cool surroundings to an electrically heated room, after starting them on a diet including pulverized inert material. We believe that we thus obtained far better results than we could have obtained by depending upon favorable changes in the weather but in most cases the results were not striking. We now believe that we failed to get better results because the humidity of our hot room was not controlled and was often low and the artificial heat did not interfere as much with the food intake as the sultry weather which followed the cooler weather of spring. Besides this, we used younger rats in most of our later work and younger rats eat more continuously. We also tried to produce intestinal stasis by restricting the food intake periodically but this made the animals restless and did not serve the purpose as well as sultry weather. In addition to this, we fed some rats pulverized materials with diets deficient in vitamin B, in the hope that this would produce the desired stasis, but again the results were unsatisfactory. The stasis due to vitamin B deficiency did not seem to be a sufficiently acute type. Nevertheless, we believe that the single case of polyposis which we observed among our early autopsies in a rat that had not been fed pulverized inert material was partly due to stasis caused by a vitamin B deficiency. Incidentally, this case shows that polyposis can occur without the use of any form of inert material and our opinion is that pulverized materials simply serve to greatly increase the incidence of intestinal stasis and of fecal conditions which cause intestinal bleeding and/or polyposis under more common conditions.

SUMMARY

Various degrees of polyposis of the colon were produced in 86 (34%) of a group of 250 rats fed diets including pulverized inert materials (kaolin, barium sulphate, talcum powder and pulverized cellulose). Bleeding of the colon occurred in about 90% of the 250 rats.

Intestinal stasis together with fecal conditions producing suction or traction upon the intestinal wall are believed to lead to the development of polyposis.

Clinical Disorders with Associated Hepatic and Renal Manifestations, with Especial Reference to the So-Called "Hepatorenal Syndrome"*

By

S. S. LICHTMAN, M.D.

and

A. R. SOHVAL, M.D.

NEW YORK, NEW YORK

IT has long been recognized that reciprocal physiological relationships exist between the functions of the liver and the kidney. Their clinical importance, however, has not been fully appreciated. It can be acknowledged that infections and intoxications may simultaneously injure the liver and kidney, and also that renal disease or dysfunction may expose latent liver disease. Recently, a type of renal failure has been linked with trauma to the liver or surgical operations on the biliary tract (28, 32-36, 54). Uremia was

attributed to renal lesions claimed to be due to the action of specific (28, 33-36) or non-specific (13, 2) nephrotoxic agents liberated from necrotic or infected liver tissue.

The clinical label, "hepatorenal syndrome," has been receiving increasing and indiscriminate usage, on the one hand, to designate all types of disorders in which both organs are involved, and on the other hand, to indicate a special type of case, on the false premise that a specific clinical entity exists.

A comprehensive study of clinical and experimental material in the literature and of cases observed by us has helped clarify the matter. A basis for the classification of the types of cases which have associated disorders of the liver and kidney was evolved.

CLASSIFICATION

The basis for classification depends on etiology and also on the temporal relationship between involvement of the liver and kidney.

I. Systemic Disorders Involving Liver and Kidneys.
   - A. Infections—Spirochetal Jaundice (Weil's Disease).
   - B. Intoxications — Apiol; Chloroform; Thyrotoxicosis; Cantharides (48); "Dioxan" (5); Pregnancy; Blackwater Fever; Transfusion Anuria with Liver Necrosis (12).
   - C. Localization of Systemic Diseases of the Liver and Kidneys
     1. Erythroblastosis.
     2. Generalized Arteritis (see Fig. 1), Periarteritis Nodosa.
     3. Diseases of the Hematopoietic System.

II. Primary Liver Disease with Renal Manifestations.
   - A. Liver Degeneration with Anuria, Oliguria and Azotemia.
   - B. Traumatic Necrosis of the Liver with Secondary Necrotizing Nephrosis.
   - C. Biliary Tract Diseases with Anuria.
     1. Without Surgical Procedure.
     2. Following Surgical Procedure.
   - D. Latent Liver Disease Exposed by Alterations in Renal Function.
   - E. Neoplasms of the Liver and Bile Passages with Anuria.
   - F. Hydatid Disease of the Liver with Secondary Necrotizing Nephrosis.
   - G. General Infections with Jaundice, Anuria, and Azotemia.

III.
   - A. Primary Renal Disease Complicated by Hepatic Disease
   - B. Diseases of the Liver and Kidney Caused Mechanically. Obstructive Jaundice Due to Enlarged Kidney.

IV. *Metabolic.*
   - A. Glycogenic Hepatonephromegaly (von Gierke's Disease) (29).
   - B. Cystinuria and Jaundice.
   - C. Addison's Disease with Azotemia and Jaundice (30).

An attempt was made to elucidate the circumstances responsible for the appearance of renal manifestations, i.e. oliguria, anuria, azotemia, renal lesions, in the group of cases designated as belonging to the hepatorenal syndrome. The following phases of the matter were considered:

1. The role played by surgical procedure, anesthesia, and jaundice.
2. The significance of anatomical and functional changes in the kidney.
3. The importance of the function of the liver in the regulation of water and mineral balance.
4. The relationship of this group of cases to other clinical disorders with analogous renal manifestations but without hepatic and biliary tract disease.
5. The existence of a specific relationship between the liver injury or infection and renal lesions or manifestations: The question of a specific form of intoxication?

THE ROLE OF SURGICAL PROCEDURE, ANESTHESIA AND JAUNDICE IN THE PRODUCTION OF THE RENAL MANIFESTATIONS

The possible role of surgical intervention in precipitating the events which lead to renal disturbances was suggested by the picture of renal failure which occurs not uncommonly following procedures on the biliary tract and then not due to shock, vomiting or dehydration. This picture occurs only rarely following other types of operations. A direct relationship between the

procedure and the ensuing events was accepted by surgeons. At first, the anesthesia and its effect on liver function was incriminated. However, cases occurred when spinal anesthesia was employed. Errors in operative technic, such as accidental ligation of an anomalous hepatic artery branch were also suspected but necropsy findings in fatal cases did not substantiate the suspicion. Sudden decompression of the biliary tract in cases of biliary obstruction were blamed for hepatic and renal failure. However, the entire picture has occurred in cases of gall stones without jaundice.

Cases have come under our observation and others have been reported in the literature indicating that surgical and adjunct procedures are unnecessary in the production of the renal manifestations. These may be considered under the following categories:

1. Acute and subacute atrophy of the liver with jaundice, anuria and azotemia.
2. Biliary tract disease, usually with cholangitis.
3. Malignancy of the liver or biliary tract with anuria and azotemia.
4. General infections and intoxications with jaundice, anuria and azotemia.

CASE REPORTS

Group 1. Liver Atrophy. Case No. 1. No. 376003, E. S.—Subacute Yellow Atrophy of the Liver with Anuria and Uremia. Biopsy of Kidney. Necrotizing Nephrosis.

A Negro, aged 28 years, with a history of lues, developed a dull pain in his lower back, chilliness, fulness in the epigastric region, fever, nausea, vomiting and diarrhea. Jaundice was first noted in the hospital, when he was admitted to the service of Dr. B. S. Oppenheimer. Edema of the eyelids persisted throughout the illness. The systolic blood pressure rose to 150 millimeters of mercury. The urinary output rapidly diminished (30 c.c. in 24 hours). The urine contained albumin, leucocytes, and erythrocytes. The blood Wassermann reaction was 4 plus. Blood analyses showed a rise in urea nitrogen to 143 milligrams per 100 cubic centimeters; plasma chlorides 490, 410 and 455 milligrams (hypochloremia); carbon dioxide combining power 47 volumes per cent, creatinin 9 to 20 milligrams, and proteins 7.2 per cent. The blood volume was slightly reduced to 61 cubic centimeters per kilogram. The blood icterus was 150 and bilirubin 8 milligrams per 100 cubic centimeters.

Intravenous glucose therapy and decapsulation of the kidneys did not produce a decrease in azotemia. The patient lapsed into semi-stupor and died in a convulsion.

The necropsy revealed subacute liver atrophy. The renal findings confirmed the histological findings reported by Dr. Paul Klemperer on biopsy material (Fig. 2A and B). Severe tubular degeneration with regeneration and acute inflammation of the stroma secondary to the tubular damage was noted. Leucocytes and casts were present in the lumen of the tubules. Most glomerular tufts were intact save for degeneration of the outer capsular epithelium. The general picture was that of a degenerative nephrosis secondary to the liver degeneration. Careful chemical analysis eliminated potassium chlorate and mercury poisoning. The biopsy findings indicated that the renal findings were not the result of postmortem change.

Group 2. Biliary tract disease. Case No. 2. No. 320978, C. U.—Acute and Chronic Cholecystitis, Cholelithiasis, Chronic Cholangitis with Jaundice, Anuria, Azotemia.

A female, aged 53 years, was admitted with a history of pain in the right hypochondrium, nausea, vomiting, anorexia, pruritus, and constipation for a period of three days. Twenty-four hours after admission she ceased voiding urine and became slightly icteric. A huge tender mass was felt in the right hypochondrium and considered to be a swollen liver. The stool contained bile. The urine contained no bilirubin. The patient was anuric for 72 hours, then began to void an ounce of dilute urine daily. The blood urea nitrogen mounted from 23 milligrams per 100 cubic centimeters steadily to 187 milligrams, despite establishment of diuresis of 2425 cubic centimeters on the thirteenth day. On admission, the blood bilirubin was 4.5 milligrams per 100 cubic centimeters. In three days this dropped to a latent jaundice with an icterus index of 15. The bromsulphalein test showed a normal result. Tyrosine was not demonstrated in the urine by the tyrosinase method (42). The urinary output and chemical findings in the blood are tabulated in Table I.

After 24 days of high carbohydrate diet and fluid intake the azotemia disappeared. The size of the liver receded to normal after the first week in the hospital. During convalescence, the patient developed a suppurative parotitis with staphylococcemia. This proved fatal despite surgical drainage. These circumstances afforded the opportunity of making observations on a subject who had just recovered from a combination of events ordinarily described as the "hepatorenal syndrome."

The cause of death revealed by necropsy was a staphylococcic endocarditis complicating the parotitis. An acute and chronic cholecystitis, gall stones, and chronic cholangitis was found. The gall bladder was huge, filled with stones, and markedly thickened. The sudden change in size of the liver during life could not be explained by the pathological findings. There was no microscopic evidence in the liver and kidney to account for the clinical picture. Apart from some minor changes in the nuclei of some of the liver cells, the liver appeared to be normal.

DISCUSSION

The *outstanding features in this case* were the adequate fluid intake by mouth throughout the course of events, the absence of surgical intervention, initial slight hypochloremia and normal blood chlorides thereafter, and the progressive increase in azotemia despite diuresis and adequate fluid intake by mouth. A Volhard concentration test indicated isosthenuria with specific gravity fixed at 1.008 and 1.010.

The elevation of amino-acids in the blood may indicate that the liver function was seriously impaired, at least temporarily, even though pigment excretion was only slightly disturbed or may be interpreted as evidence of extensive generalized tissue breakdown. The absence of tyrosine in the urine argues against liver autolysis (42). The absence of liver necrosis or evidence of recent repair or regeneration at necropsy is further support for this point of view. The traces of cholesterol ester in the blood in the early part of the disease points, however, to liver damage (20).

The chronic cholangitis may be the most significant pathological feature in the liver. This has repeatedly been found in the cases in which renal failure followed cholecystectomy. Such cases have been reported by Hoesch, Devay, Fuentes and Rubino, Merklen, Bicart and Adnot, and others.

Group 3. Cases with neoplasm of the liver or biliary passages developing anuria and azotemia have been cited by Frerichs, Gilbert, Chabrol and Benard, Koch, Hess, Schutz, Helwig and Kuhn.

Group 4. Cases of apiol poisoning with azotemia and jaundice have been reported in the French literature. Cases with general infections due to gram-positive cocci, i.e. pneumococci, streptococci, and staphylococci, with hepatic insufficiency and anuria have been recorded (Quenu and Joltrain, two cases, 1909; Widal and Abrami, one case, 1908; Rousel and de Lavergne, five cases, 1919;

Fig. 1. Acute Necrotizing Arteritis With Thrombosis in the Liver. Illustration from a case of subacute glomerulonephritis with necrotizing arteritis of the liver and pancreas and jaundice. (Clinical Pathological Conference Case Report, J. Mount Sinai Hospital, 2:286, 1936).

Savy and Thiers, one case, 1929; Lederer, one case, 1930). Hammerschlag recently reported a case of enterococcus sepsis with fever, coma, jaundice, and azotemia (150 mg. per 100 c.c. blood) with recovery.

THE ROLE OF ANATOMICAL AND FUNCTIONAL CHANGES IN THE KIDNEY IN THE DEVELOPMENT OF THE RENAL MANIFESTATIONS

Anatomical Changes. Renal lesions have been reported in connection with long standing icterus, chronic liver disease without jaundice, and in circumstances where acute infections in the biliary tract or trauma to the liver substance occur. The pathological findings as a rule do not correspond to the severity of the clinical picture.

The renal lesions dependent on jaundice have adequately been described as a "bile nephrosis" by Moebius, Fahr and Wilbur. The integrity of the glomerulus under this circumstance has been emphasized.

Renal lesions have been described in acute yellow atrophy of the liver by Frerichs, Minkowski, Kraus, Versé, Hauser. More recently, Mayer, and also Koch, have made extensive observations. The picture has been characterized as a nephro-dystrophy with fatty changes in the tubules, mainly the convoluted tubules. Rarely, the picture assumes the appearance of a necrotizing nephrosis (Our Case No. 1; Bompiani).

The renal lesions in 12 cases of acute and subacute atrophy of the liver were studied by us. The alterations were almost exclusively confined to the tubular structures, chiefly the convoluted portions. They consisted of varying degrees of degeneration (granular, hydropic, vacuolar, and fatty) admixed with different degrees of postmortem change. Nuclei were frequently pale-staining, or absent. There were occasionally bile stained casts in the tubules and rarely bile pigment in the epithelium. Although the extent of degeneration was severe in a few cases, in none was there leucocytic infiltrations, hemorrhage or edema. The glomeruli were generally normal. No correlation could be established between the presence of azotemia and the severity of the renal lesions. Severe degenerative lesions were present in the absence of azotemia. On the other hand, a case with azotemia (urea nitrogen 40 mg. per 100 c.c.) showed no significant renal tubule change. A necrotizing nephrosis was present but once (Case 1).

Hewitt (37) analyzed 10 cases with necrosis of the renal epithelium in infections and intoxications and found that five also had lesions of the liver resembling those found in acute yellow atrophy. Helwig and Orr, and Furtwaengler reported a high-grade necrotizing nephrosis in tramuatic necrosis of the liver. Mild glomerular and also interstitial changes were also noted. In cases dying of uremia following operations on the biliary tract, tubular changes have been reported in the kidney (Clairmont and Haberer, Fitz-Hugh, Steinthal). A marked nephrosis has been reported by Schutz, Helwig and Kuhn. Fuentes and Rubino suggested the name, hepatonephrosis, to describe the renal picture in this group of cases.

The renal changes must be differentiated in the presence of jaundice as to whether they are due to the cytotoxic effects of excreted bile salts, the so-called bile nephrosis, or nephrotic changes due to other toxic factors. What relationship the renal lesions bear to the clinical renal manifestations is a matter which has not as yet been settled in other forms of renal disease. However, a lack of correlation between the severity of the renal anatomical disturbance and the clinical manifestations is definite. In traumatic liver necrosis, a direct relationship between the intensity of the liver injury and the kidney damage appears to exist.

Renal Function. The reciprocal functioning of the liver for the kidney and vice versa in physiological crises affecting either organ has been demonstrated repeatedly by the phenolsulphonthalein excretion test. If one path of excretion becomes blocked, the other compensates and excretes the dye.

The specific gravity of the urine is usually normal in the presence of disease of the liver and gall bladder with or without jaundice. The concentrating power of the kidney is maintained, usually even in patients with oliguria and azotemia. Meczner (46) combined Volhard and galactose tolerance tests in 19 patients with liver disease. The specific gravity of the urine remained normal despite impairment in liver function and oliguria.

Occasionally, isosthenuria is present. In our Case No. 2 there was persistent isosthenuria despite diure-

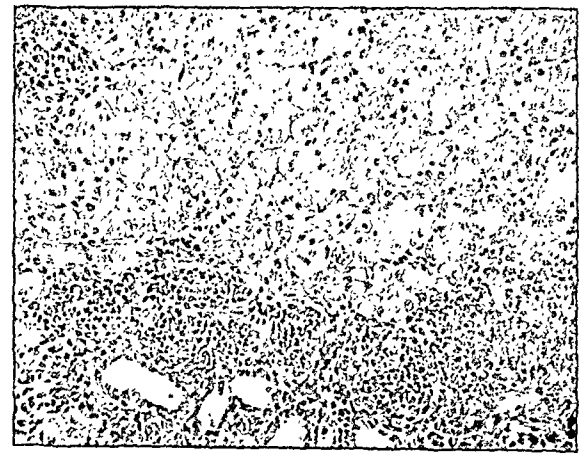

Fig. 2A. Photomicrographs. Biopsy of Kidney. Subacute Yellow Atrophy of Liver with Anuria (Case 1). Severe Tubular Degeneration with Regeneration. Acute Inflammation of the Stroma.

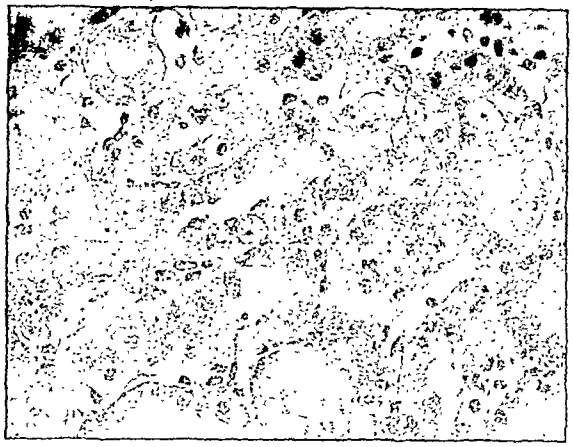

Fig. 2B. Degenerative nephrosis; higher magnification than Fig. 2A.

sis and relief from jaundice. A renal morphological basis was not demonstrable at necropsy. Koch observed isosthenuria in two cases of carcinoma of the liver with oliguria. In Weil's disease he found isosthenuria commonly, although urea clearance was normal. In acute yellow atrophy of the liver, however, he and also Hess found no deviation from the normal in the specific gravity of the urine. This has also been our experience. The renal functional disturbances when they occur appear not to be directly related to anatomical changes in the kidney.

THE REGULATION OF WATER AND ION EQUILIBRIUM BY THE LIVER

WATER ECONOMY

Numerous claims have been made that the liver is responsible in great measure for the water balance in the organism (2, 3, 4). The liver may act as a reservoir for water (49). By regulation of the minerals and chemical reaction of the blood the liver may assist in water transport. Furthermore, hormonal properties accredited to liver tissue may influence diuresis (49). The liver is concerned with the synthesis of blood proteins. Deficiency of blood proteins leads to colloid osmotic pressure changes which may cause water to leave the blood. Water tolerance tests in liver disease indicate a tendency to water retention (2, 3, 9, 10, 46).

Mineral Metabolism. It has been asserted that the liver regulates the ionic equilibrium of the body. A direct action of specific ions on liver cells has been claimed (3).

Beckmann (8) has made extensive observations on the influence of various ions injected into the portal vein. The passage of the respective ions through the liver effected changes in the water concentration of the blood. With experimental bile duct obstruction the influence of individual mineral elements was retained, whereas with liver damage the specific effect was lost and water entered the blood directly. The intact liver is necessary for this ionic equilibrium. Beckmann further studied the effect of injury of various components of liver tissue, i.e. biliary tract, parenchyma, reticulo-endothelial system, upon mineral metabolism. Only in parenchymal damage did he observe water metabolism disturbance, evidenced by prolonged and increased escape of water from the liver into the blood.

Disturbances in blood and urinary chlorides have been noted. Chloride retention has been claimed in cirrhosis of the liver and liver atrophy (40). Kahn and Barsky reported an increase in sodium and chloride in the chemical analysis of the liver in a case of acute yellow atrophy.

Sodium retention has been demonstrated in catarrhal jaundice (56). A disturbance in the inorganic salts of the blood and tissues in hepatic disease has been reported (55).

Considering the intimate roles that the liver plays in the transport of water and storage and distribution of certain ions it may be conceived that disturbances in these functions may lead to a retention of fluids and ions in the tissues. Renal manifestations may thus arise entirely on an extrarenal basis through prerenal deviation of fluids, i.e. the water is not available for excretion by the kidney.

COMMENT

Disorders occur with combined disease or functional disturbance in the liver, biliary tract and the kidney. It is clinically important to recognize whether both these organs are affected by the same etiological agent or whether either organ had previously been diseased by a chronic process. These distinctions form the basis for classification.

The label "hepatorenal syndrome" has been applied to cases of liver or gall bladder disease complicated by renal failure. First recognized by the surgeon, procedures on the biliary tract were linked with the ensuing renal events. Anesthesia, accidental ligation of an anomalous vessel, traumatic necrosis of the liver, infection in the gall bladder bed, or decompression of the biliary tract in obstructive jaundice were some of the factors incriminated. Experimental investigation was directed along these channels.

Renal lesions, essentially nephrotic in character have been produced experimentally and described clinically. They have been ascribed to specific nephrotoxins liberated from necrotic liver tissue, to vasospastic substances derived from the same source effecting spasms of the renal vessels with ischemia and necrosis of the renal epithelium, and also to nonspecific toxic effects upon renal epithelium in its physiological activity in eliminating toxic substances from the body, mainly through the convoluted tubules (36, 13).

From our own experiences and from a review of many cases in the literature it is evident that the renal changes are not constant and appear to bear no constant relationship to the severity of the clinical picture. A functional change is demonstrable in some cases as evidenced by isosthenuria.

Similar renal changes and renal functional disorganization have also been noted in ileus, intestinal intoxication of infants, and diabetic acidosis. These conditions may also be characterized by renal failure. In these conditions, the renal anatomical lesions are interpreted to play only secondary roles. The primary factor is accepted to be extra-renal.

Unfortunately, the analogy between these conditions and those belonging to the so-called "hepatorenal syndrome" has been ignored, mainly because chronologically a surgical procedure may have preceded the renal failure. However, we have observed that the

classical features may occur in cases without trauma, operation, anesthesia, or decompression of an obstructed biliary tract. Jaundice and its concomitant features need not participate.

Renal failure has occurred where vomiting was minimal, where no hypochloremia existed and where the fluid intake has been adequate as in our second case.

In ileus, diabetic acidosis, and intestinal intoxication of infants, a definite intoxication exists. Loss of water, chlorides, base, and a disturbance in acid-base equilibrium have been demonstrated. In the present group of cases, chemical findings in the blood, aside from azotemia and creatinin retention, have as yet indicated no special type of change.

Profound disturbances in water and mineral metabolism may occur with liver damage. Water, sodium, and chloride, appear to be retained, especially in liver tissue. Knowledge of the complete electrolyte pattern of blood and tissues awaits investigation of the distribution of extracellular and intracellular water and minerals. It is our belief that the results of such studies will adequately explain the mechanism of the pre-renal deviation of fluids in the cases belonging to the so-called hepatorenal syndrome. An infection or intoxication, probably, disturbs the function of the liver in regulation of water and minerals, initially. The renal lesions are caused by this same factor, primarily, or possibly by the chemical changes brought about by the prerenal deviation of fluids.

There is no evidence for the existence of a specific relationship between the disturbance in the liver and the renal manifestations. The use of the term, "hepatorenal syndrome" should therefore be discouraged.

SUMMARY

Clinical disorders in which infection or intoxication involves the liver and kidney in the same pathological process have been distinguished from those in which liver damage or biliary tract infection antedates renal manifestations. A point has been made of recognizing the significance of acute disease of either the liver or kidney when it supervenes upon chronic disease of the other organ.

The renal manifestations which may occur in the course of degenerative disease of the liver, biliary tract infections, malignancy of the liver and bile passages, trauma to the liver or following surgical procedures upon the biliary tract are ascribed by us to abnormal extra-renal conditions due to hepatic dysfunction. The liver functions concerned with the regulation of water and mineral balance are markedly disturbed. Anuria and azotemia, under these conditions, result from pre-renal deviation of fluids. Water is not available for renal excretion. Surgical procedures, jaundice, shock, decompression of an obstructed biliary tract and vomiting are not essential factors in producing the renal manifestations in this group of cases.

The nephrotic lesions which have been found in some of these cases, occur inconstantly and do not determine the clinical renal manifestations. They are rather an indication of a profound intoxication or they may be caused by disturbed extra-renal conditions.

Analogous renal manifestations occur in other clinical disorders, i.e. diabetic acidosis, ileus, and intestinal intoxications of infants, and are associated with known chemical changes in the blood and tissues. No specific relationship between liver damage or infection in the biliary tract and the renal manifestations has been demonstrated. The underlying chemical nature of this intoxication and its effects is unknown. The use of the clinical label, "hepatorenal syndrome" is to be avoided.

R. A. ARENS, M.D., JACOB MEYER, M.D.

and

H. NECHELES, M.D., Ph.D.

CHICAGO, ILLINOIS

IN an earlier paper we have described a technic for and the results of subtotal gastrectomy (s.g.) for duodenal and gastric ulcer (1). In the five years following this publication a number of patients have been studied in detail in the Department of Gastro-Intestinal Physiology, founded since then. The present paper deals with the size of the postoperative stomach, emptying time (E.T.), hunger contractions (H.C.), direct observations of the mucosa by gastroscopy, secretion and blood findings, and clinical end results of patients following subtotal gastric resection. For obvious reasons not all of the tests could be performed on every patient and at the same date. An attempt is made to interpret subjective symptoms with the changes in gastric physiology. Forty-four ulcer patients were selected at random from the gastro-intestinal clinic of Michael Reese Hospital; all were white, 36 males and 8 females. The age (at time of operation) varied from 21 to 54 with an average of 39 years. Nine of the patients had been operated on previously at other institutions, a gastro-enterostomy or pyloroplasty having been performed. The final diagnosis of the 44 cases were—30 duodenal ulcer (D.U.), 5 gastric ulcer (G.U.), 3 gastric and duodenal ulcer, 6 gastrojejunal ulcer (G.J.U.). One patient diagnosed with gastric ulcer also had a gastro-enterostomy and ulcer of the stomach occurred just above the stoma (No. 32). One patient with a gastrojejunal ulcer also had a recurrence of his duodenal ulcer (No. 36).

RESULTS

1. Emptying Time and Size of Stomach. Method: Using a milk barium mixture the emptying time was determined by fluoroscopy before and after operation. In some cases repeated examinations were done. The normal average emptying time by our method is from 3½ to 4½ hours in the intact stomach. An estimation of the size of the stump was made from the X-ray film in the post-operative examination. The average period of time after operation was 3 years (2 weeks to 14 years). It is evident that the E.T. was diminished very considerably in most patients; in some of them emptying times as short as 15 and 20 minutes are recorded, whereas before operation the values were 270 and 330 minutes respectively (Nos. 13 and 28). In other instances subtotal gastrectomy produced little or no change in E.T., as seen in No. 5 (60 and 80 minutes, G.E.), in No. 10 (270 and 240+ minutes), and in No. 18 (240+++ and 240+++ minutes, G.E.).

*From the Departments of Surgery, Internal Medicine and Gastro-Intestinal Physiology of the Michael Reese Hospital, Chicago.

†Aided by the Oscar Aberle Fund.
We are indebted to Drs. R. Schindler and W. L. Palmer of the Department of Medicine, University of Chicago, for doing the gastroscopies and for permission to use the facilities of the Clinic.

The complete tables of this paper can be obtained from Dr. H. Necheles, Department of Gastro-Intestinal Physiology, Michael Reese Hospital.

Submitted October 22, 1936.

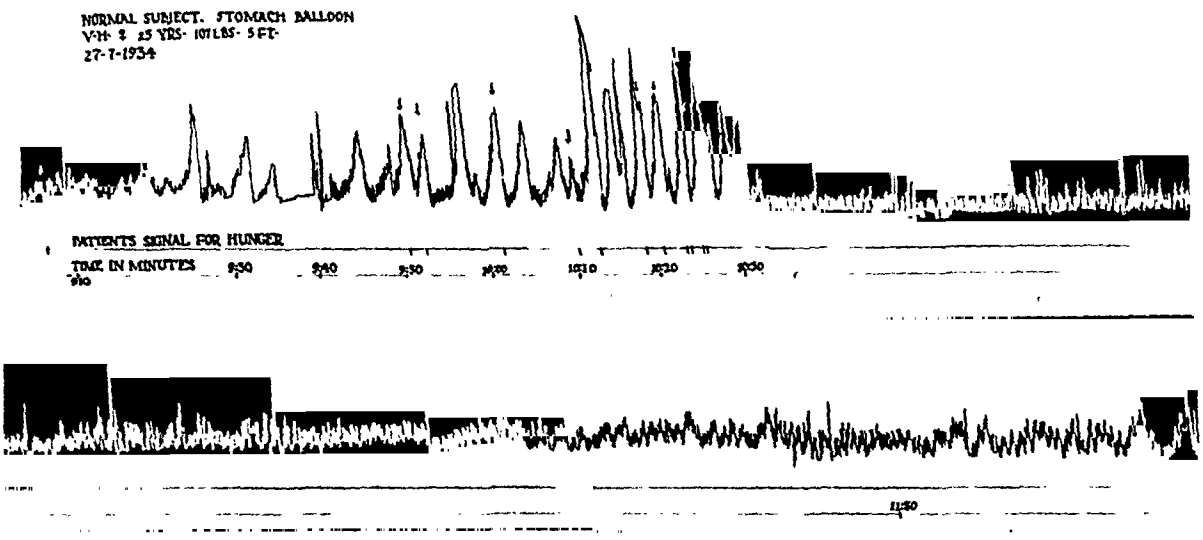

Fig. 1

Fast emptying of the resected stomach may persist for many years (No. 13, E.T. 15 minutes, six years after operation, also Nos. 1, 21, 23, 28 and 35). In the course of time, in some patients the E.T. changes while in others it remains remarkably constant. Moreover, some patients showed a decreasing emptying time, whereas others showed the reverse. In this connection it ought to be mentioned that in some patients the size of the stump of the remaining stomach increases as time progresses (Nos. 9, 10, 17, 34, 36 and 42). This is similar to what occurs in dogs after wide resection of their stomachs, and it may influence E.T. It may also explain why patients immediately after operation can eat only small meals, but are able to increase the size of the meals as time goes on. In a few cases the size of the stump diminishes gradually (Nos. 1 and 4). It is puzzling, that such short E.T. as 15-30 minutes did not produce clinical symptoms except possibly in one case (No. 13). Distention of the duodenum produces pain and nausea. It may either be that the liquid barium meal is not an adequate functional test, or that in these patients no backflow into the proximal loop of the gastro-enterostomy occurs. Dr. R. Schindler*, believes that gastrectomies are followed by good results clinically, if they function like the pyloric sphincter, and in two of our patients he observed such action and demonstrated it to some of us, (Nos. 5 and 6). The E.T. in these two instances were 80 and 60 minutes respectively, which is considered as normal in a subtotal gastric resection. In these two patients a normal mucosa of the stomach was reported and the clinical end result was considered to be satisfactory.

A comparison between E.T. and postoperative results fails to reveal consistent relationship between satisfactory clinical results and longer or shorter E.T. The E.T. in the patients called clinically satisfactory varied between 20 and + 240 minutes with an average of 92 minutes (29 cases). One patient with occasional epigastric distress (No. 9) had an E.T. of 95 minutes, and the unsatisfactory patients (Nos. 13, 36, 38 and 39) had E.T.'s of 15, 105, 60 and 75 minutes respectively.

Comparison between size of the stump of the stomach and E.T. reveals a possible relationship. Five patients with 1/5-1/4 of the stomach left, had an average E.T. of 72 minutes, 20 patients with 1/3 of the stomach left, had an average E.T. of 91 minutes and 4 patients with 1/2-2/3 of the stomach left, had an average E.T. of 80 minutes. A comparison between the size of the stump of the postoperative stomach and clinical end results fails to produce evidence of relationship. Patients with satisfactory clinical results (24 cases) had an average stump of 34% (25%-66%); unsatisfactory clinical results had an average stump of 31% (25%-33%, 4 patients); and one patient with occasional epigastric distress had a stump of 50% (i.e. half the size of the original stomach).

TYPE OF HUNGER CONTRACTIONS

Methods: Gastric motility in the fasting state (12-14 hours p.c.) was studied and recorded by the balloon-manometer method described by Carlson (2). The tests lasted from 2 to 4-1/2 hours. In the following discussion Type I denotes tonus waves, Type II denotes hunger contractions and Type III denotes hunger contractions of tetanic type. The regularity of periodic recurrence of rest and activity and the number and height of hunger contractions was considered also. Figure 1, representing the periods of hunger and rest of the stomach of a normal student, illustrates the normal occurrence of Type I, II and III.

Thirty-one motility tests were performed on 23 patients at an average interval of one year between operation and test (2 weeks to 4 years and 4 months). In three patients studies were made before and after operation, in two before operation, only, and in 18 after operation only. In those in whom the tests were repeated at varying intervals after operation, identical results were obtained. Thus, repeated motility tests were performed in patient No. 2, 11 months, 11 1/2 months, and 12 1/2 months after operation. In patient No. 3, 11 and 16 months, and in patient No. 34, 1 1/2 months and 1 year after operation.

*Now Gastroscopist of Michael Reese Hospital.

RESULTS

In the motility tests there was no normal variation between periods of hunger motility and rest, as exemplified in Figure 1. In 2 patients (Nos. 32 and 34) practically only tonus waves were recorded, while in the rest of the tests continuous motility was observed with very short and irregular periods of rest intervening. By irregular we refer to deviations from the typical course of a period of hunger contractions, as described by Carlson (2) and as partly exemplified in Figure 1.

Figure 2 shows one such test done six months after operation on patient No. 28. In this, as well as in some other cases, the contractions appeared to be more of the intestinal than of the gastric type. We are certain, however, that the balloon was in the stomach. In the three patients observed before and after subtotal gastric resection practically the same type of motility was found in both instances. In only one patient was tetanus observed (No. 4).

The patients registered (electric signal) Type II and III contractions as hunger pangs although they did not signal at every such contraction. No significant change in the frequency of hunger pangs was noted in the three persons before and after operation.

In 18 patients (not tabulated) of whom we thought that subtotal gastrectomy would be performed sooner or later, motility tests were recorded. All of them had an established diagnosis of duodenal ulcer. Seventeen were male, 1 female. Normal periodicity was observed in only two persons; atonia obtained in two tests; in one of these severe epigastric pain developed. Irregular periodicity occurred in six tests. In 8 tests constant activity prevailed. Type III contractions were not observed in this series.

Figure 3 represents a tracing from one of the ulcer patients with continuous gastric motility.

GASTROSCOPIC FINDINGS

Seventeen patients were gastroscoped by Dr. R. Schindler. The gastroscopic visualization of gastrojejunal ulcer was verified by X-ray examination and by the clinical history in one instance (No. 36). A normal mucosa was reported in four patients, while in remaining patients gastritis or erosions were observed. In two instances a pylorus-like functioning of the gastrojejunal stoma was reported.

GASTRIC ANALYSIS

Methods: Histamine tests were done as described by us in a previous paper (3), 0.35 mg. of histamine acid phosphate being injected subcutaneously. In the case of postoperative tests the stomach contents were aspirated through a Levin tube with constant suction, and each small sample tested separately for free acid, as also described previously (4). The latter method is important in cases of subtotal gastric resection, because it detects free acid, where other methods frequently fail. The Ewald meal employed was identical in character and technic with that described by Vanzant, Alvarez, Eusterman, Dunn and Berkson (5). In three tests alcohol was used as secretagogue, 100 c.c. of a 7% solution being employed. Forty-six histamine and 20 Ewald tests were made. On a number of patients more than one test was performed, but only the last one made (i.e. longest period since operation) is being reported. In a number of patients Ewald tests were made before operation and Histamine tests after operation.

Results: It is not surprising that after subtotal gastrectomy large residual contents of the fasting stomach would be absent (Nos. 29 and 31), and that little residue is found in all cases. The degree of acidity of the fasting secretion (basal) of the stomach is of importance, since we find it high in a great number of cases with duodenal ulcer. It probably is due to the high nocturnal acid secretion in duodenal ulcer patients as described by Sippy, Rehfuss and Hawk, Winkelstein, Palmer and others (6). In the case of the partly resected stomach, the free acidity of its residual contents either diminishes considerably or drops to zero. This occurred in 11 cases while in Nos. 16, 28, 29 and 36 the free acidity was either higher than before operation, or not appreciably diminished. Following a stimulus (histamine in most tests), the acid secretion was higher in 2 patients than before operation (No. 18 and 36) in 4 patients no significant change took place, the acid secretion remaining high (Nos. 2, 3, 4, 16), in 7 there was a considerable reduction in free acidity (of 50% and more), and in 18 patients no free acidity was found. This means that of 31 patients observed, 25 showed either greatly reduced or no free acid secretion to a secretory stimulus after subtotal gastrectomy. Repeated

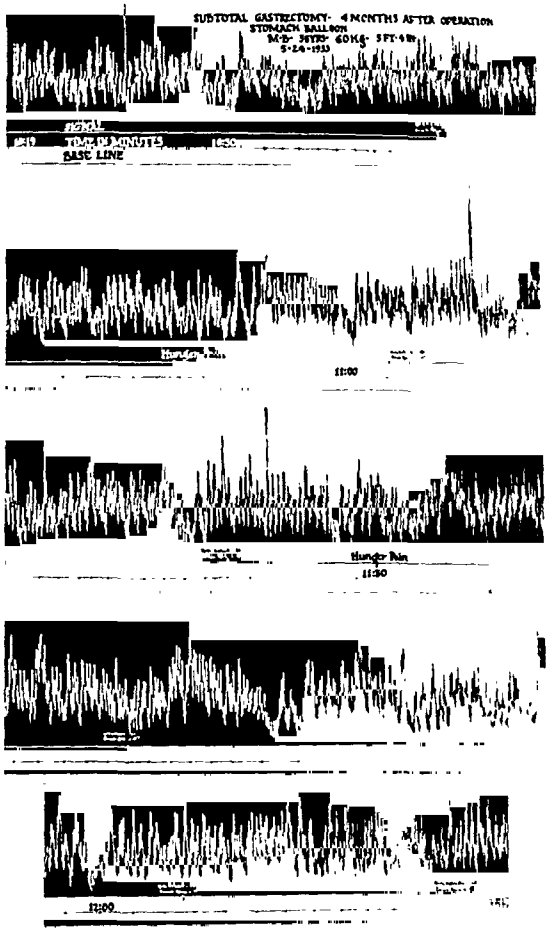

Fig. 2

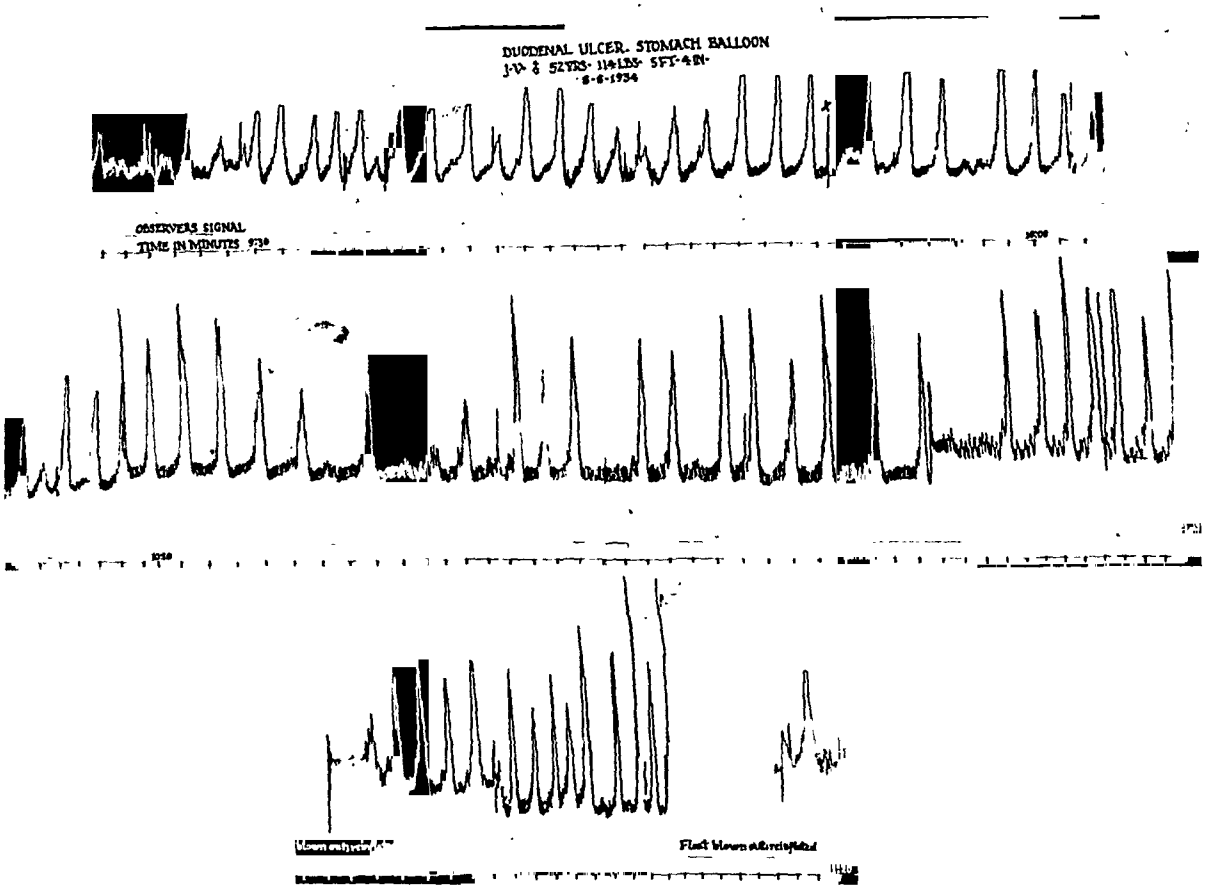

Fig. 3

tests of stomach secretion following histamine were performed on 10 patients, with intervals of from 1 to 48 months after operation. Constant suction and fractional testing of small samples were done in every case (4). In nine out of 10 patients free acid disappeared after operation. In one patient the acidity stayed high (No. 4), and in 2 patients a moderate degree of free acidity returned 2 years and 1 year after operation (Nos. 2 and 44). In another patient the acidity of the residual contents of the stomach (see above) was increased considerably 8 months after operation, while the response to histamine remained low. This is important, because residual acidity probably is closely related to night secretion, which has been reported to be high in patients with duodenal ulcer (see above). It is of interest therefore, that high acidity of residual contents returned 8 months after operation, and that considerable free acidity following histamine stimulation was found 1 and 2 years after operation.

BLOOD PICTURE

In the following discussion blood findings are considered satisfactory when the red blood count was above 4,000,000 and hemoglobin above 70%; below these marks the patient is designated anemic. Of 28 patients observed before, and later than 6 months after operation, 6 had distinct anemia after operation. (Nos. 15, 18, 28, 30, 31 and 41). Three showed no considerable change of their red cell count and hemoglobin, 12 had definite improvement of one or both, and in 9 a decrease of red cell count and hemoglobin or both took place, but no anemia occurred. It is difficult to evaluate these findings, because we are not certain whether all of the patients conscientiously took the iron compounds given to them. No case of pernicious anemia was found. No eosinophilia occurred in this group as one might expect if the theory of vagotonia and resultant frequent eosinophilia were true. In a number of patients the monocyte count seemed somewhat high and in a number of patients the lymphocyte count changed after operation, in most cases showing an increase. But these changes seem to be too small to invite speculation.

CLINICAL END RESULTS

As "Clinical end results" the opinion of the Internist is presented, with due consideration of the opinion of the patients. In the majority of the cases the opinions of physician and patient are in accord, but in a few, in which distinct psychoneurotic traits were apparent, and in which complaints of the patient seemed to be without reasonable basis only the opinion of the physician is given. "Satisfactory" means no complaints and ability to work; "unsatisfactory" denotes complaints and inability to work; occasional epigastric distress (in No. 9) denotes unquestionable improvement from a previous state of more or less constant epigastric distress; yet the treating Inter-

nist is not quite satisfied with the condition of the patient; due to dietary indiscretion or alcoholism, occasional gastric distress of slight nature sometimes appears.

Forty-four patients have been followed closely enough to be included in the following discussion. Of these, 37 present satisfactory end results (group A), 2 have occasional epigastric distress (group B) and 5 are classed as unsatisfactory (Group C), of this latter group only one is diagnosed as gastrojejunal ulcer (No. 36). What findings have group A, B, and C, in common?

(1) *Body weight:* In 22 patients gains are recorded after operation. Increase in body weight occurred only in persons classed as "satisfactory clinical end results." In 6 patients distinct loss of weight occurred (below 2 kg.). Three of these are classed as satisfactory (one of them being psychoneurotic), one as occasional epigastric distress, and 3 as unsatisfactory, one of them being diagnosed as gastrojejunal ulcer.

(2) *Emptying Time of Stomach:* Thirty-five observations on clinical end results and emptying time are recorded. Of these 7 had a short E.T. of 15-30 minutes, while the rest of the 28 had an E.T. from 30 to +240 minutes. The group with short E.T. contains 5 satisfactory end results and 2 unsatisfactory end results. The group with longer E.T. contains 24 satisfactory and 3 unsatisfactory end results, and one patient with occasional epigastric distress.

(3) *Hunger Motility of the Stomach:* Hunger motility of the stomach was irregular in all of the 19 patients studied. Of these 18 presented "satisfactory clinical end results" and one "unsatisfactory clinical end results."

(4) *Size of Postoperative Stomach:* Of 29 observations 20 showed 1/3 (a), i.e. the approximate size of stomach soon after operation. Five showed 1/4 to 1/5 (b), i.e. a decrease of size of stomach after operation, and 4 showed 1/2 (c) to 2/3, i.e. increased size of stomach after operation. Group (a) contained 17 cases of satisfactory and 3 cases of unsatisfactory end results. Group (b) had 4 satisfactory and one unsatisfactory end results; the unsatisfactory case had the smallest stomach observed in the group (1/5, No. 38). Of Group (c), 3 cases are satisfactory end results and one has occasional epigastric distress.

(5) *Gastroscopy:* Of the 17 cases included in this group, four appeared normal and 13 presented pathologic appearance. All of the normal cases are grouped as satisfactory end results. Of the second group 10 are satisfactory end results, one patient has occasional epigastric distress and 2 are considered unsatisfactory end results.

(6) *Gastric Analysis:* Of 37 patients end results are classified as satisfactory in 31 and in 4 as unsatisfactory, while 2 had occasional epigastric distress. The group of 31 satisfactory end results contains 8 patients with moderate amounts of free acid after stimulation, 3 patients with high acid response and 20 with low response or anacidity. The second group (unsatisfactory end results) contains one patient with a high acid response (G.J.U.) and 3 with low acid or anacidity. One patient of the group with occasional epigastric distress has anacidity, the other a moderate degree of acidity.

(7) *Blood:* Of 30 patients 24 blood findings are classified as satisfactory (a) and 6 as anemia (b). Group (a) contains 19 satisfactory and 4 unsatisfactory clinical end results, and one patient with occasional epigastric distress. All six patients of group (b) (anemia) are classed as satisfactory clinical end results.

DISCUSSION AND CONCLUSIONS

It appears that gain or loss of body weight follows the clinical end results. Only one patient classified as a satisfactory end result lost considerably in weight but this patient is a psychoneurotic (No. 8). All the remaining "satisfactory end results," had small losses of weight, remained stationary or gained weight. One patient with occasional epigastric pain lost 2.5 kg. (No. 9), one with gastrojejunal ulcer lost 3.8 kg. (No. 36) while the "unsatisfactory end results" lost 7 and 4 kg. (Nos. 13 and 43 respectively). Therefore it seems indicated to follow body weights of such patients as indicator of clinical improvement.

In analysing the emptying time of the postoperative stomach it appears that slower emptying time offers better clinical end results than rapid emptying time.

No correlation can be found between hunger motility and clinical end results. It is concluded tentatively that although in practically all cases with irregular hunger motility satisfactory clinical end results were found, yet a functional irregularity present before operation remains. No correlation between clinical end results, and size of gastric stump could be detected. The difficulty of estimating gastric size by X-ray makes the size of the stump a questionable value in determining end results of subtotal gastrectomy.

No correlation can be seen between gastroscopic findings and clinical end results, even after grouping the gastric findings into moderate and severe pathology of the gastric mucosa (Nos. 1, 8 and 42). One case of G.J.U. apparently was diagnosed as such.

Analysis of gastric secretion shows that no correlation exists in this clinical group between high or low free acidity and clinical end results. In the group with satisfactory clinical end results the greatest incidence of high acid response was found. The patient with gastrojejunal ulcer had a high free acid in the unstimulated and stimulated stomach, but the other unsatisfactory end results, including the patient with occasional epigastric distress have moderate or low acid response or anacidity.

Studies of the red blood count and hemoglobin show a negative correlation with clinical end results. Normal blood findings occurred in the unsatisfactory clinical end results, and all 6 cases of anemia appeared as satisfactory clinical end results.

Von Haberer's clinic (7) reports as a striking feature after gastric resections the absence of motor disturbance and of abnormal roentgenological signs on the one hand and the frequent subjective complaints on the other, and a fairly rapid emptying, but no dumping. The same was reported in more detail recently (8). Raydin and his co-workers using different test meals conclude that the mechanism by which the postoperative stomach empties itself is similar to the normal stomach with the pylorus intact, and that it does not depend on the size of the stoma (17). Wilensky and Crohn (9) report that following partial gastrectomy in only a minority of cases does the stomach return to an almost normal state of functional activity (balloon method). The same was reported by Rogers

(10), but he did not find regular hunger pangs associated with hunger contractions in his patient. Shapiro and Berg (11) and Fauley, Strauss and Ivy (12) report the effects of subtotal gastrectomy on dogs; acid secretion gradually returned to its original level. Walters (13) reports that relative achlorhydria does not occur in all cases of subtotal gastric resection in man. We have to consider, however, the gastric pathology before operation, as well as the occurrence of gastritis after operation, which will modify the gastric acid response to a stimulus. Therefore it would be desirable to gastroscope a group of patients a number of times before and after subtotal gastrectomy. Lewison and Ginsberg (14) in a previous paper observed permanent achlorhydria in the majority of their cases, but Klein (15) found a higher incidence of acid secretion in a similar group of patients. In a recent paper Milanes (16) reports hypermotility and a great incidence of histamine refractory achlorhydria after subtotal gastric resection. It is not possible to review the entire literature, but the above quotations and our own findings give evidence of the many contradictions in most of the functional problems involved in subtotal gastrectomy. In addition one must bear in mind not only the different methods of resection, but also the variations in each of them, not only modifications, but also slight and perhaps unconscious variations from case to case in the hands of the same skilled operator. Individual conditions and postoperative changes (like adhesions) probably make the outcome of each case somewhat different. To the great number of physical factors must also be added the various psychic ones and the importance of the sociological background (including nutrition) of the individual patients. The frequent subjective complaints, in our experience are present during the first six months after operation. In those patients who have definite social or economical conflicts either antedating or following the operation the subjective complaints continue for a long period and do not disappear. Perhaps they only disappear after proper social adjustment and medical therapy.

SUMMARY

In a group of 44 patients the body weight, emptying time, size, motility and secretion of the stomach, its mucosa by gastroscopy, and the erythrocyte and differential count and hemoglobin was studied. The body weight seemed to be a fairly good indicator of postoperative results after subtotal gastric resection. The results of all functional tests and observations performed varied too much to be considered as reliable indicators of clinical end results.

The Pathogenicity of Four Strains of Endamoeba Histolytica from Chicago*

By

HENRY E. MELENEY, M.D.

and

WILLIAM W. FRYE, Ph.D.

NASHVILLE, TENNESSEE

ON March 14, 1934, we received from the Department of Health of Chicago, Illinois, four strains of *Endamoeba histolytica* which had been obtained from persons in that city. Previous to this time we had been studying the pathogenicity of various strains of *E. histolytica* for kittens (1). Five strains from Tennessee had been studied and it had been found that two of these, obtained from a community in the hill region of Middle Tennessee, produced a lower incidence of infection than the other three strains obtained from a community in the bottom-land of West

*From the Department of Preventive Medicine and Public Health, Vanderbilt University School of Medicine, Nashville, Tennessee.

Submitted December 16, 1936.

Tennessee. In the hill community 38 per cent of the inhabitants had been found to harbor *E. histolytica*, but there was no evidence of occurrence of acute amoebic dysentery, whereas in the bottom-land community only 19 per cent of the inhabitants had been found to harbor *E. histolytica*, but twenty-five cases of acute amoebic dysentery had occurred during the past two and a half years.

TABLE 1

Pathogenic indices of four strains of E. histolytica from Tennessee repeatedly tested in kittens

Average number of days since isolation of culture	Number of kittens inoculated	Kittens developing infection		Pathogenic index
		Number	Per cent	
Strain A-1 (Hill Country)				
220	38	12	31.6	0.58
600	20	4	20.0	0.54
957	21	8	38.0	0.57
1023	24	7	29.2	0.53
1053	20	6	30.0	0.58
1329	25	8	32.0	0.50
1774	20	5	25.0	0.57
Strain A-2 (Hill Country)				
222	19	15	79.0	0.49

958	22	7	31.8	0.65
1082	21	8	38.1	0.58
1328	23	7	30.4	0.67
Strain B-1 (Bottom-land)				
180	20	12	60.0	1.06
602	20	11	55.0	1.01
875	25	16	64.0	1.09
1036	24	20	83.3	1.25
1047	20	13	65.0	1.28
1279	24	12	50.0	1.05
1745	29	20	69.0	1.19
Strain B-2 (Bottom-land)				
186	20	13	65.0	1.15
612	11	5	45.0	1.35
1071	20	12	60.0	1.31
1320	20	11	55.0	1.32

In the performance of the above experiments we kept all strains of the amoebae in culture on similar media consisting of an egg-Ringer base overlaid with horse serum-Ringer (1-6) with the addition of sterile rice flour. Kittens were inoculated by direct injection into the ileum following laparotomy, and twenty or more kittens, usually weighing between 200 and 600 grams, were inoculated in each experiment. The pathogenic activity of each strain of amoebae was determined by classifying the colons of successfully infected kittens at autopsy into nine classes according to the extent and severity of the lesions. Since time was an important element in the development of lesions, the number of days each kitten survived after inoculation was recorded and the "pathology produced per day" was calculated by dividing the number of the class to which each colon was assigned by the number of days of survival after inoculation. The average of these quotients for a series of twenty or more kittens was designated the "pathogenic index" of the strain of *E. histolytica* employed (2). We have tested four of the Tennessee strains at intervals over a period of nearly five years and have found that each strain has maintained a fairly constant pathogenic index. The two strains from the hill region have constantly given a low pathogenic index, whereas the two strains from the bottom-land have constantly given a high pathogenic index. The results of these experiments are presented in Table 1.

It is the purpose of this paper to record similar experiments performed with the four strains of *E. histolytica* received from Chicago. These strains are designated C-1, C-2, C-3 and C-4. They were isolated from the following cases:

Strain C-1: J. P., white male, age 26, engineer in a manufacturing plant in which a survey for *E. histolytica* was made because of water contamination. He had had no symptoms referable to amoebiasis. Cysts of *E. histolytica* were found in the stools and the organism was recovered in culture.

Strain C-2: M. B., white female, age 23, maid employed in the hotel which was the chief source of the epidemic of amoebic dysentery in 1933. There was no history of symptoms referable to amoebiasis. Cysts of *E. histolytica* were found in the stools and the organism was recovered in culture.

Strain C-3: L. L., white male, age 54, waiter employed during July, 1933, at the hotel which was the chief source of the epidemic of amoebic dysentery. Early in July he developed a bloody diarrhea and was

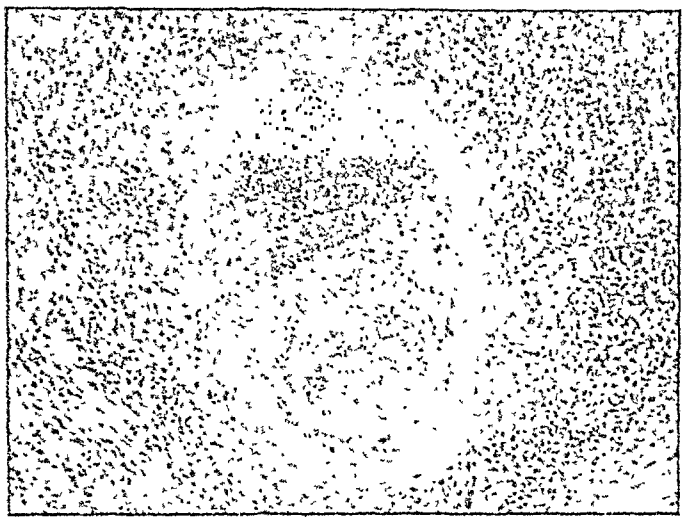

Fig. 1. Acute Necrotizing Arteritis With Thrombosis in the Liver. Illustration from a case of subacute glomerulonephritis with necrotizing arteritis of the liver and pancreas and jaundice. (Clinical Pathological Conference Case Report, J. Mount Sinai Hospital, 2:286, 1936).

Savy and Thiers, one case, 1929; Lederer, one case, 1930). Hammerschlag recently reported a case of enterococcus sepsis with fever, coma, jaundice, and azotemia (150 mg. per 100 c.c. blood) with recovery.

THE ROLE OF ANATOMICAL AND FUNCTIONAL CHANGES IN THE KIDNEY IN THE DEVELOPMENT OF THE RENAL MANIFESTATIONS

Anatomical Changes. Renal lesions have been reported in connection with long standing icterus, chronic liver disease without jaundice, and in circumstances where acute infections in the biliary tract or trauma to the liver substance occur. The pathological findings as a rule do not correspond to the severity of the clinical picture.

The renal lesions dependent on jaundice have adequately been described as a "bile nephrosis" by Moebius, Fahr and Wilbur. The integrity of the glomerulus under this circumstance has been emphasized.

Renal lesions have been described in acute yellow atrophy of the liver by Frerichs, Minkowski, Kraus, Versé, Hauser. More recently, Mayer, and also Koch, have made extensive observations. The picture has been characterized as a nephro-dystrophy with fatty changes in the tubules, mainly the convoluted tubules. Rarely, the picture assumes the appearance of a necrotizing nephrosis (Our Case No. 1; Bompiani).

The renal lesions in 12 cases of acute and subacute atrophy of the liver were studied by us. The alterations were almost exclusively confined to the tubular structures, chiefly the convoluted portions. They consisted of varying degrees of degeneration (granular, hydropic, vacuolar, and fatty) admixed with different degrees of postmortem change. Nuclei were frequently pale-staining, or absent. There were occasionally bile stained casts in the tubules and rarely bile pigment in the epithelium. Although the extent of degeneration was severe in a few cases, in none was there leucocytic infiltrations, hemorrhage or edema. The glomeruli were generally normal. No correlation could be established between the presence of azotemia and the severity of the renal lesions. Severe degenerative lesions were present in the absence of azotemia. On the other hand, a case with azotemia (urea nitrogen 40 mg. per 100 c.c.) showed no significant renal tubule change. A necrotizing nephrosis was present but once (Case 1).

Hewitt (37) analyzed 10 cases with necrosis of the renal epithelium in infections and intoxications and found that five also had lesions of the liver resembling those found in acute yellow atrophy. Helwig and Orr, and Furtwaengler reported a high-grade necrotizing nephrosis in tramuatic necrosis of the liver. Mild glomerular and also interstitial changes were also noted. In cases dying of uremia following operations on the biliary tract, tubular changes have been reported in the kidney (Clairmont and Haberer, Fitz-Hugh, Steinthal). A marked nephrosis has been reported by Schutz, Helwig and Kuhn. Fuentes and Rubino suggested the name, hepatonephrosis, to describe the renal picture in this group of cases.

The renal changes must be differentiated in the presence of jaundice as to whether they are due to the cytotoxic effects of excreted bile salts, the so-called bile nephrosis, or nephrotic changes due to other toxic factors. What relationship the renal lesions bear to the clinical renal manifestations is a matter which has not as yet been settled in other forms of renal disease. However, a lack of correlation between the severity of the renal anatomical disturbance and the clinical manifestations is definite. In traumatic liver necrosis, a direct relationship between the intensity of the liver injury and the kidney damage appears to exist.

Renal Function. The reciprocal functioning of the liver for the kidney and vice versa in physiological crises affecting either organ has been demonstrated repeatedly by the phenolsulphonthalein excretion test. If one path of excretion becomes blocked, the other compensates and excretes the dye.

The specific gravity of the urine is usually normal in the presence of disease of the liver and gall bladder with or without jaundice. The concentrating power of the kidney is maintained, usually even in patients with oliguria and azotemia. Meczner (46) combined Volhard and galactose tolerance tests in 19 patients with liver disease. The specific gravity of the urine remained normal despite impairment in liver function and oliguria.

Occasionally, isosthenuria is present. In our Case No. 2 there was persistent isosthenuria despite diure-

The Relationship Between Oral and Gastric Bacterial Flora*

By

MARION HOOD, Ph.D.

and

LLOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

THE relationship between the bacterial flora of the oral and gastric regions has received little attention, although considerable work has been done upon the flora in each locality. The correlation or interdependence of the two types of microbic population seems to have been given but scant consideration.

Various observers have attempted to show that certain retrogressive or degenerative oral lesions, such as pyorrhea, seeded the stomach and upper levels of the intestinal tract with pyogenic bacteria, derived from the mouth. Hurst, (1924) (1927) (1933) has called attention for many years to the importance of pyogenic foci in the mouth, throat and nose upon gastric and duodenal bacterial flora.

The present work classifies the organisms cultured from the mouth and stomach and determines the relation which these bear to each other. Effort has been made to discover the effect of continuous entrance of the exogenous flora and to study the protective mechanism by which the body defends itself against this entrance.

GENERAL TECHNIC

All experiments were performed on patients in the medical wards of the Research and Educational Hospital of the University of Illinois, College of Medicine. Although none of these persons could be considered entirely normal from a health standpoint, those exhibiting any particular dysfunction of the gastro-intestinal tract or suffering from primary anemias were not used. Cultures were made on plain agar from material aspirated from the stomach, if only the possibility of growth was to be determined. For classification, blood agar and Endo plates, as well as sugars for biochemical reactions were also used. No anaerobic cultures were made. For culturing the stomach contents one standard platinum loop of material was placed on the surface of solid media and distributed with a sterile glass spreader which was then carried to a second similar plate. To obtain cultures from the mouth, sterile swabs were rubbed across the back of the tongue, then passed twice across a sterile agar plate. With a second sterile applicator the material was spread over the surface. This swab was then carried to the second plate. By this procedure sufficient dilution was usually obtained to procure well isolated colonies.

Hydrogen ion concentration was the method used for determining the acidity of the various substances. The colorimetric method was employed using standard buffers made according to the specifications of Clark (1928). All buffers were standardized by a Leeds Northrup potentiometer. The hydrogen ion concentration gives the effective acid concentration which is the most important factor limiting bacterial growth. When control tests showed that the hydrogen ion concentration of the stomach contents was too acid to make probable the growth of organisms, varying amounts of buffered alkali made according to Clark (1928) were added. It was difficult to alkalinize the stomach. There are several possible explanations for this fact. The alkali may have passed directly through the stomach into the duodenum or it may have stimulated increased acid secretion according to Boldyreff's (1914) principle of the self-regulation of the acidity of gastric contents. The alkali was sometimes given in milk in an effort to stabilize the acid-base balance as described by Arnold and Brody (1926).

EXPERIMENTAL PROCEDURES

Experiment I: The Relation Between the Oral and Gastric Bacterial Flora. Twenty-five fasting stomachs were aspirated by means of Rehfuss tubes. Cultures were made from this material and at the same time from the mouths to determine whether or not the micro-organisms cultured from the oral cavities were similar to those found in the stomach contents as reported by Bartle and Harkins (1925) and Kopeloff (1922).

In a series of sixteen cases a preliminary procedure was carried out to determine whether there was variation in the flora in different parts of the mouth. Cultures were taken from the lips, the tip of the tongue, the back of the tongue, the gums, and from the saliva. As was also found by Arnold and Stuart (1935) there was some variation in

*From the Research Laboratories of the Illinois Department of Public Health and the Department of Bacteriology and Public Health, and the Department of Medicine, University of Illinois, College of Medicine.

Submitted October 7, 1936.

classical features may occur in cases without trauma, operation, anesthesia, or decompression of an obstructed biliary tract. Jaundice and its concomitant features need not participate.

Renal failure has occurred where vomiting was minimal, where no hypochloremia existed and where the fluid intake has been adequate as in our second case.

In ileus, diabetic acidosis, and intestinal intoxication of infants, a definite intoxication exists. Loss of water, chlorides, base, and a disturbance in acid-base equilibrium have been demonstrated. In the present group of cases, chemical findings in the blood, aside from azotemia and creatinin retention, have as yet indicated no special type of change.

Profound disturbances in water and mineral metabolism may occur with liver damage. Water, sodium, and chloride, appear to be retained, especially in liver tissue. Knowledge of the complete electrolyte pattern of blood and tissues awaits investigation of the distribution of extracellular and intracellular water and minerals. It is our belief that the results of such studies will adequately explain the mechanism of the pre-renal deviation of fluids in the cases belonging to the so-called hepatorenal syndrome. An infection or intoxication, probably, disturbs the function of the liver in regulation of water and minerals, initially. The renal lesions are caused by this same factor, primarily, or possibly by the chemical changes brought about by the prerenal deviation of fluids.

There is no evidence for the existence of a specific relationship between the disturbance in the liver and the renal manifestations. The use of the term, "hepatorenal syndrome" should therefore be discouraged.

SUMMARY

Clinical disorders in which infection or intoxication involves the liver and kidney in the same pathological process have been distinguished from those in which liver damage or biliary tract infection antedates renal manifestations. A point has been made of recognizing the significance of acute disease of either the liver or kidney when it supervenes upon chronic disease of the other organ.

The renal manifestations which may occur in the course of degenerative disease of the liver, biliary tract infections, malignancy of the liver and bile passages, trauma to the liver or following surgical procedures upon the biliary tract are ascribed by us to abnormal extra-renal conditions due to hepatic dysfunction. The liver functions concerned with the regulation of water and mineral balance are markedly disturbed. Anuria and azotemia, under these conditions, result from pre-renal deviation of fluids. Water is not available for renal excretion. Surgical procedures, jaundice, shock, decompression of an obstructed biliary tract and vomiting are not essential factors in producing the renal manifestations in this group of cases.

The nephrotic lesions which have been found in some of these cases, occur inconstantly and do not determine the clinical renal manifestations. They are rather an indication of a profound intoxication or they may be caused by disturbed extra-renal conditions.

Analogous renal manifestations occur in other clinical disorders, i.e. diabetic acidosis, ileus, and intestinal intoxications of infants, and are associated with known chemical changes in the blood and tissues. No specific relationship between liver damage or infection in the biliary tract and the renal manifestations has been demonstrated. The underlying chemical nature of this intoxication and its effects is unknown. The use of the clinical label, "hepatorenal syndrome" is to be avoided.

latter both before and after the deflection of the saliva from the stomach. This was done in the hope that the comparison of these results might determine whether or not the swallowed saliva exerted a noticeable influence on the hydrogen ion concentration and the bacterial population of the gastric contents. Although the tests were made at ten minute intervals over a two hour period no significant change could be noted in any case, either in the hydrogen ion concentration of the gastric contents or in the number of colonies in the cultures from the three sources. The results are shown in Graph III. Bell and MacAdam (1924) reported no change in the acidity of the stomach when the saliva was withheld. Kopeloff (1922) concluded from his work that the continued swallowing of saliva is the chief factor which determines the bacterial content of the stomach.

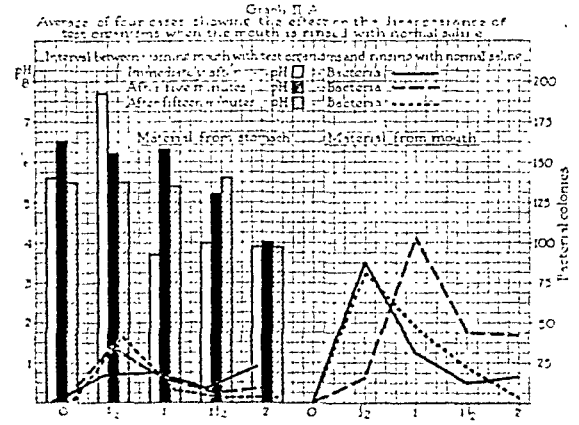
Experiment V: The Number of Organisms in the Saliva During Twenty-Four Hours.

Although the preceding series of cases showed no diminution in the number of colonies cultured from the gastric contents when the saliva was removed, it seemed advisable to culture the collected saliva and estimate the approximate number of organisms per cubic centimeter. The total amount removed during the two hour period was well mixed and dilutions were made from 1:2 up to 1:64. From a pipette which delivered fifteen drops per cubic centimeter, one drop of each of the dilutions was plated out on plain agar plates. The colonies from the culture showing best dilution were counted and the number of organisms per cubic centimeter computed. The amount of saliva per twenty-four hours calculated on the basis of the two hour observed period varied from 264 c.c. to 2280 c.c. and the estimated number of culturable bacteria for this twenty-four hour amount varied from 2,592,000 to 79,120,800. The following table gives the summary of the results.

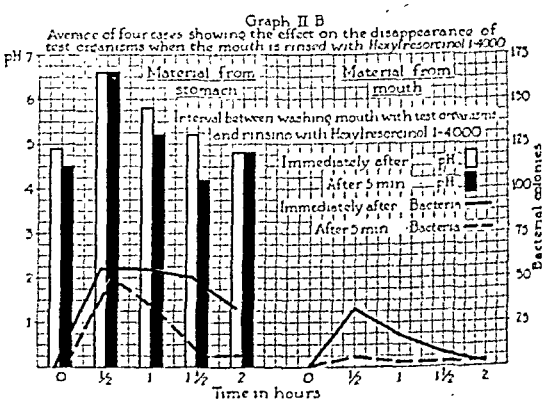
The number of micro-organisms in the saliva secreted during twenty-four hours

Case Patient	I No. 44976	II No. 45351	III No. 45600	IV No 45677	V No. 45103
Amount of saliva in two hours	70 c.c.	163 c.c.	22 c.c.	40 c.c.	190 c.c.
Amount of saliva in twenty-four hours	840 c.c.	1956 c.c.	264 c.c.	480 c.c.	220 c.c.
Number of colonies per c.c.	6240	19,000	299,700	14,400	48,000
Number culturable bacteria per twenty-four hours	5,241,600	35,208,000	79,120,800	2,592,000	41,040,000

*Calculated on basis of two hour observed period.



All tests were made between eight and ten a.m. before the patients had eaten breakfast. This may account for the fact that in general both the amount of saliva and the number of bacteria per cubic centimeter were less in this group of experiments than had been reported by other workers.



Crowley and Richet (1935), using different technic found a much higher bacterial count per cubic centimeter of saliva. Their experiment was directed toward producing growth of the maximum number of organisms, while in the present case the interest lay in comparing the growth findings from the saliva with those obtained from the gastric contents, therefore similar technic was used for both.

Hawk and Bergeim (1931) stated that the amount of saliva secreted by an adult is from 1000 to 1500 c.c. per twenty-four hours. Zaus and Fosdick (1934) reported that the basal flow of saliva averaged 0.5 c.c. per minute or 720 c.c. per twenty-four hours. During stimulation the amount increased to 2.5 c.c. per minute or 3600 c.c. per twenty-four hours. According to the counts made by Feirer and Leonard (1931) approximately 2,788,000 organisms could be grown on plain agar from 1 c.c. of fluid used as a mouth wash. They noted that there is a marked increase in organisms during the day even when no food is taken.

DISCUSSION

Cultures from the mouth and stomach show a striking similarity in bacterial flora. This must mean that the oral flora is present in the stomach either as a

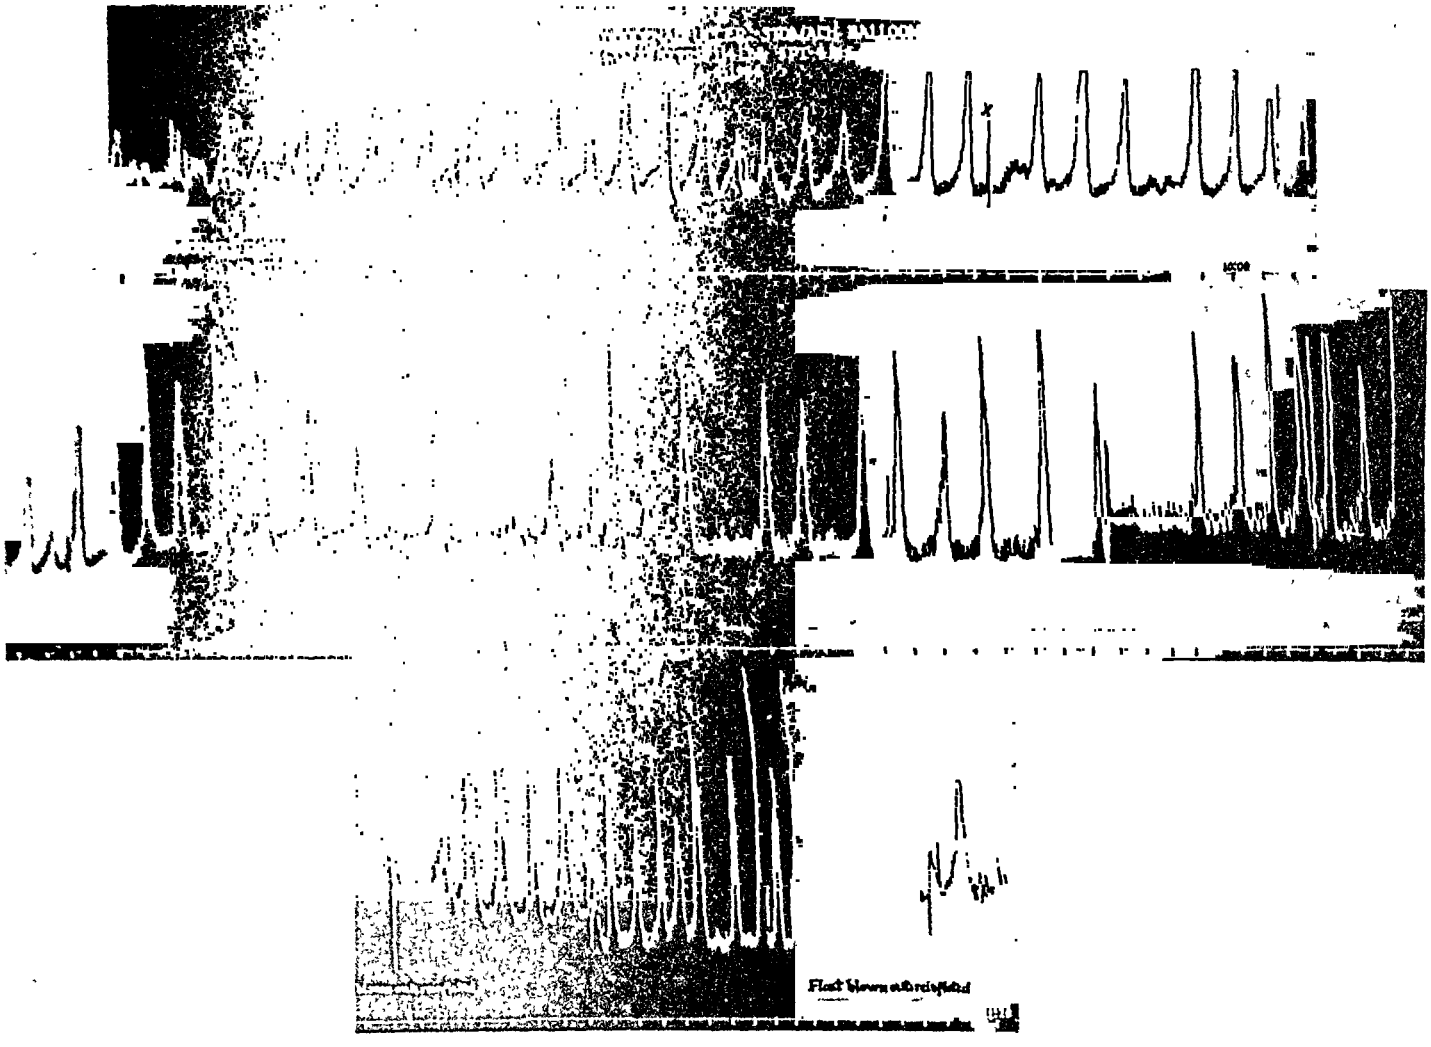


Fig. 3

tests of stomach secretion following histamine were performed on 10 patients, with intervals of from 1 to 48 months after operation. Constant suction and fractional testing of small samples were done in every case (4). In nine out of 10 patients free acid disappeared after operation. In one patient the acidity stayed high (No. 4), and in 2 patients a moderate degree of free acidity returned 2 years and 1 year after operation (Nos. 2 and 44). In another patient the acidity of the residual contents of the stomach (see above) was increased considerably 8 months after operation, while the response to histamine remained low. This is important, because residual acidity probably is closely related to night secretion, which has been reported to be high in patients with duodenal ulcer (see above). It is of interest therefore, that high acidity of residual contents returned 8 months after operation, and that considerable free acidity following histamine stimulation was found 1 and 2 years after operation.

BLOOD PICTURE

In the following discussion blood findings are considered satisfactory when the red blood count was above 4,000,000 and hemoglobin above 70%; below these marks the patient is designated anemic. Of 28 patients observed before, and later than 6 months after operation, 6 had distinct anemia after operation. (Nos. 15, 18, 28, 30, 31 and 41). Three showed no considerable change of their red cell count and hemoglobin, 12 had definite improvement of one or both, and in 9 a decrease of red cell count and hemoglobin or both took place, but no anemia occurred. It is difficult to evaluate these findings, because we are not certain whether all of the patients conscientiously took the iron compounds given to them. No case of pernicious anemia was found. No eosinophilia occurred in this group as one might expect if the theory of vagotonia and resultant frequent eosinophilia were true. In a number of patients the monocyte count seemed somewhat high and in a number of patients the lymphocyte count changed after operation, in most cases showing an increase. But these changes seem to be too small to invite speculation.

CLINICAL END RESULTS

As "Clinical end results" the opinion of the Internist is presented, with due consideration of the opinion of the patients. In the majority of the cases the opinions of physician and patient are in accord, but in a few, in which distinct psychoneurotic traits were apparent, and in which complaints of the patient seemed to be without reasonable basis only the opinion of the physician is given. "Satisfactory" means no complaints and ability to work; "unsatisfactory" denotes complaints and inability to work; occasional epigastric distress (in No. 9) denotes unquestionable improvement from a previous state of more or less constant epigastric distress; yet the treating Inter-

Atresia of the Pylorus

By

RICHARD J. BENNETT, Jr., M.D., M.S.*
EDMONTON, ALBERTA, CANADA

IT has been computed from statistics that atresia in any portion of the gastro-intestinal tract occurs about once in every ten thousand births (1). Such anomalies, according to DeLee, occur frequently in cases of hydramnios. The case of atresia which I am reporting is one in which there was a definite gap in the continuity of the lumen of the pylorus.

CASE REPORT

History. A female baby, weighing seven pounds and three ounces was delivered after a twenty-four hour labor. Three hundred ounces of amniotic fluid were measured. The child took its feedings well but always vomited within an hour. The stools during the first four days after delivery consisted of a small amount of meconium.

Examination. There was marked distention of the abdomen. No pyloric tumor could be palpated. A rectal examination revealed no abnormalities. The child, having lost twenty-four ounces in weight, was examined under the fluoroscope. The stomach nearly filled the entire abdomen. Barium was introduced into the stomach by means of a catheter and examination fluoroscopically gave

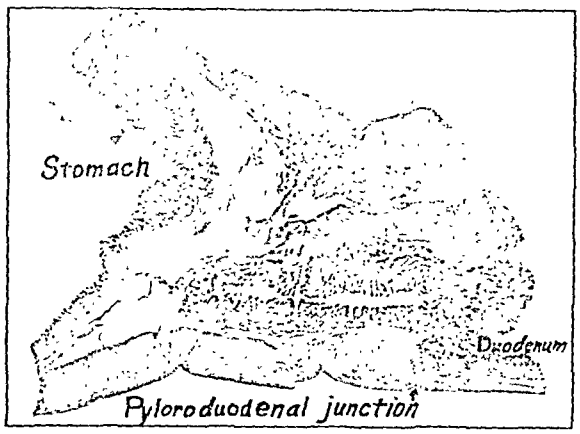

Fig. 1. Pyloroduodenal junction showing atresia of pylorus. Hematoxylin-eosin stain; x6.

further evidence of a markedly dilated stomach. Apparently no gas or barium passed into the duodenum. A barium enema revealed no abnormalities. A diagnosis was made of hypertrophic pyloric stenosis.

Treatment. The usual anti-spasmodic medical measures having been of no avail, it was deemed advisable to relieve the condition by surgical means. Using local ½% novocain, a 3 cm. upper right rectus incision was made through the abdominal wall. The stomach was four times normal size with a definite 1½ cm. tumor at the pylorus beyond which there was a marked reduction in the diameter of the small intestine. The large bowel was not entirely collapsed. It was thought best to do a Rammstedt type of pyloroplasty. A 1 cm. longitudinal incision was made over the central portion of the pyloric tumor the incision being carried through the serous and muscular layers until the mucosa bulged well. A small piece of gastrohepatic omentum was sutured to the inferior border of the pylorus so that the bulging mucous membrane was covered. The operation being finished, 30 c.c. of warm normal saline solution were poured into the abdominal cavity and the abdomen was closed without drainage.

Following operation, fluids given by mouth were not retained. The general condition at this time was critical and the baby expired thirty-six hours after operation.

Autopsy. There were no significant findings except those present in the gastro-intestinal tract. The esophagus was dilated to a diameter of 1 cm. Examination of the abdomen revealed an enormously dilated stomach with an enlarged and firm pylorus. Incision of the Rammstedt type of operation was present on the anterior aspect of the pylorus and was found to be satisfactory. A probe could not be passed from the pylorus to the stomach or vice versa. The small intestine was collapsed. The cecum was enlarged and contained some barium. The large bowel showed nothing of note.

Microscopic. Serial longitudinal sections studied microscopically revealed a 1 mm. lack of continuity in the lumen of the pylorus, 5½ mm. proximal to the pyloroduodenal junction. There was no evidence of epithelial-lined lumen joining proximal and distal pylorus.

DISCUSSION

For congenital atresia of the pylorus and the first portion of the duodenum, I would suggest that a long pliable wire within a catheter be passed down the esophagus into the stomach with the abdomen open. Once in the stomach, the pliable wire could be pushed a short distance beyond the catheter and placed against the offending septum. The proximal end of the wire would then be fitted into the usual handle of the electro-surgical unit, the power being turned on and off as desired. The catheter protected wire could be manipulated through the stomach wall by means of the right hand and the left hand could palpate the anomalous part to estimate when a suitable sized opening had been completed. In a very short operating time, an intra-intestinal method of producing gastro-intestinal continuity could thus be performed avoiding peritonitis which is so often fatal in the newborn.

ally as Editor of the American Journal of Digestive Diseases and Nutrition. His untimely passing leaves a void that will be difficult to fill.

Frank C. Yeomans, New York City.

It was with deepest regret that I learned of the death of Doctor Smithies. I know none of us can replace the tremendous energizing stimulus and intelligence he exerted over the activities of the medical profession, especially our gastro-enterological group and the Journal.

A. H. Aaron, Buffalo, N. Y.

I was shocked to learn of the untimely death of Doctor Smithies. I have known him for years as a courageous and indomitable fighter for those principles he regarded as right. Although never anxious for indiscriminate friendships, Frank Smithies had an unusual capacity for personal loyalty.

Curtice Rosser, Dallas, Texas.

Genial, brilliant and forceful Frank Smithies has been one of the outstanding figures in American gastro-enterology for the past two or three decades. He, perhaps, has done more to advance the scientific study of gastro-enterology than any of our confreres. His contributions to the literature on gastro-enterology have been valuable and stimulating to others of us engaged in the study and treatment of abdominal diseases. Perhaps the crowning piece of constructive work in Frank Smithies' career was his cooperation in the upbuilding of a high class journal devoted entirely to digestive diseases and nutrition. This publication will be continued and will receive the hearty support of every man interested in internal diseases.

Seale Harris, Birmingham, Alabama.

I was shocked to hear the news of the death of Doctor Smithies. He was one of the most dynamic and energetic men of my acquaintance. His passing is a loss of the first magnitude to the cause of scientific gastro-enterology in America. All of us who knew him marvelled at the amount of productive work he has been able to turn out, year after year. He was always a courageous leader, a sincere critic and an accomplished clinician. His editorial work on the American Journal of Digestive Diseases and Nutrition was his last major accomplishment and it will continue to be a monument to his memory and an evidence of his ability.

H. L. Bockus, Philadelphia, Pa.

I was closely associated with Doctor Smithies in gastro-enterologic work here in the Mayo Clinic a number of years ago. He always impressed me with his great native ability, industry, enthusiasm and studiousness. In addition to his scientific qualifications and achievements, his interests were wide. He was a model husband and a devoted father, and his genial personality endeared him to his friends. He was a prolific writer and his achievements in the field of science were enviable. These accomplishments, in addition to the fact that he was one of the founders of the American College of Physicians, and Editor of the American Journal of Digestive Diseases and Nutrition, which he also helped to found, should assure him a permanent place in American Medicine.

Geo. B. Eusterman, Rochester, Minn.

I was indeed shocked and grieved to hear of the death of Doctor Smithies. My contact with him dated back to 1917 when I was at the University of Illinois, College of Medicine. There, both as a student and a member of the faculty, I came in rather intimate contact with Dr. Smithies. In our class, at least, he was considered one of the finest teachers of medicine we had and we all looked forward to his classes and particularly to his clinics. He always treated his students as colleagues and I never saw him show anything but the kindest interest in their welfare. His lectures were beautifully organized and he made a profound impression on his students. To those of us who knew him personally his loss is great and we will remember him with affection.

T. B. Magath, Rochester, Minn.

The entire medical profession, and particularly those of us who have known him intimately and followed his work in recent years, grieves at the sudden and untimely death of Dr. Frank Smithies. He represents one of the figures making for real progress in medicine. His boundless energy and wealth of ideas stimulated many of his coworkers, professional friends and enemies, to continued improvement of methods used in professional practice and new fact finding. Frank Smithies had a personality which stimulated all who came in contact with it. He was instrumental in starting many medical advances which will live as monuments. Perhaps some of the most outstanding were his activity in the inaugurating of the American College of Physicians and his editorial activities for the American Journal of Digestive Diseases and Nutrition. We shall all suffer by his departure.

J. A. Bargen, Rochester, Minn.

I have been closely connected with the founding and subsequent development of the American College of Physicians as Regent, Governor and Secretary-General, and during a good part of that extended period I was in constant contact with Dr. Smithies. Those of us who had the good fortune to be in touch with College affairs at that time know full well that it was he, almost single handed, who saved it from disaster and set it upon the road to a highly successful and useful career.

Dr. Smithies for several years devoted more of his time, each day, to College affairs than to his private practice. More than this he spent for the College generously of his own money, at a time when the finances were in a precarious state. Of these personal expenditures he kept no account and for them he was never reimbursed.

Second only to his immediate family was the American College of Physicians, his chief concern in his daily life. The American College of Physicians owes Frank Smithies an everlasting debt of gratitude.

Wm. Gerry Morgan, Washington, D. C.

I have learned with profound sorrow of the death of Dr. Frank Smithies, an indefatigable worker, an outstanding clinician, a discriminating specialist, a voracious reader, a prolific writer, an efficient editor, a loyal friend, who will be sorely missed in the various fields of activities by the many with whom he came in contact. His death represents a severe loss to the profession which he adorned.

Irvin Abell, Louisville, Ky.

While I knew that Dr. Smithies had not been well for some time, I was terribly shocked to hear of his sudden passing away. Needless to say, I do not have to tell you what a tremendous loss our Association suffers and how grieved his very many friends both in the Association and at large will be on learning of his death. He was certainly a splendid fellow and always very frank. I had become very fond of him and admired him more and more for his tireless energy and enthusiasm under the load of the physical handicap that he bore so well.

Russell S. Boles, Philadelphia, Pa.

I was indeed shocked to learn of Dr. Smithies' death, because the last time I saw him he was so perfectly well, and it seems impossible that he is dead. The Journal of Digestive Diseases and Nutrition will undoubtedly suffer a great deal by his loss. I have known Dr. Smithies for the past twenty years, first learning to know him while I was an extern at the Augustana Hospital in Chicago. I have never known a man who deserves more credit to have accomplished the things he has in spite of his infirmity. He was strictly honest, thoroughly reliable, and a great friend of the young man. Even as a young extern

"In Memoriam"

FRANK SMITHIES, M. D., Sc. D., M. A. C. P., 1880—1937

Obituary

Dr. Frank Smithies passed away Tuesday morning, February 9, 1937, following a cerebral hemorrhage.

He was born in Elland, England, December 21, 1880, and came to the United States when a very young child and had his elementary school education in Philadelphia and Chicago. He was a graduate of the Calumet High School of Chicago and studied medicine at the University of Michigan from which school he was graduated in 1904. Following this he went abroad and studied at the University of Berlin and Guy's Hospital, London.

After returning to this country he taught at the Rush Medical College, 1904-05, and then at the University of Michigan, 1906-10. He then went to Mayo Clinic, Rochester, Minn., where he worked in the Department of Gastro-enterology from 1911-14. After this he returned to Chicago where he practiced Diagnostic Medicine with especial reference to Diseases of the Digestive System. From 1915-25 he was professor of medicine at the University of Illinois. He was Attending Physician, Henrotin Hospital since 1921; Chief of Clinic in Digestive Diseases, Municipal Tuberculosis Sanitarium, Chicago, 1927-30; Consulting Physician of the C. M. and St. P. R. R.

He made many contributions to the medical literature. His papers numbered well over one hundred, including his book on Cancer of the Stomach, published in 1916. He was Editor-in-chief of the American Journal of Digestive Diseases and Nutrition and Associate Editor of the American Journal of Syphilis (St. Louis), Annals of Internal Medicine (Lancaster), and American Journal of Tropical Medicine (Baltimore).

He was past president of the following societies: American College of Physicians, 1927-28; American Gastro-Enterological Association, 1929-30; American Society of Tropical Medicine, 1931-32; American Therapeutic Society, 1932-33.

His hobbies were reading and fishing. He collected many rare books and was particularly interested in books on arctic explorations, of which he had an unusually large collection.

In 1917 he was made a fellow of the American College of Physicians, and elected a member of the council of the College, and later created one of the four *Masters*.

Dr. Smithies did not seek honors, they came to him in recognition of his scientific attainments. He had been for many years a very active member of the American Gastro-Enterological Association bringing to its meetings many excellent papers always presenting clear cut, unequivocal statements which amplified and illuminated the subject. He was a past president of this association.

He understood so well people and motives, which, with his dynamic personality, aided him greatly in the practice of medicine and medical organization. His diligence and vision were a great influence in establishing the American College of Physicians on a permanent foundation.

Our Editor-in-chief, Frank Smithies, now belongs to the past, and as time goes on we will more truly know his distinctly journalistic qualities and his masterful knowledge of gastro-enterology. The latter was encyclopedic in scope and gave to our journal at once a preëmminence in its sphere.

Clement R. Jones, Pittsburgh, Pa.

In the death of Dr. Frank Smithies, the medical profession has suffered an unusual loss. As teacher and writer his ability was outstanding. His teaching of gastro-enterology was characterized by a vigorous and original approach to old problems, by clear, masterful thinking, and by lucid expression. These native qualities were made still more effective by a colorful personality. As a speaker before various national and state medical societies, his services were ever in demand, deeply appreciated, and cheerfully given. A keen, critical sense was one of his outstanding attainments; and he exerted a most stimulating influence upon younger medical men. As Co-Founder and Editor-in-chief of the American Journal of Digestive Diseases and Nutrition, he has made a lasting contribution. Truly, he was one of the outstanding medical figures of this generation.

John G. Mateer, Detroit, Michigan.

In the death of Frank Smithies the medical profession as a whole, and especially those devoted to intensive study of digestive problems, have lost a wise adviser and an acknowledged leader. His contributions have been many and varied in the field of diseases of the stomach and intestine, while his indomitable courage and indefatigable energy unquestionably have been of inestimable value to his many students, medical friends and patients. His loss is a very real one and will be deeply felt by everyone who has come in contact with him personally or who has been helped by his work and character.

Thomas R. Brown, Baltimore, Md.

The untimely demise of Frank Smithies robs science of a scholar of international stature, deprives mankind of a noted benefactor, and afflicts his friends with an irreparable loss.

It was a privilege to have studied under him at the University of Michigan, and a still greater privilege to have been an intimate friend for over thirty years. Friendship for Frank Smithies had a deep-seated foundation of admiration for his intellectual achievements. The list of his literary contributions to medical science, beginning in 1904, has been extensive. He was a leading authority on gastro-intestinal diseases, and his share in the alleviation of human misery shall never be accurately gauged. His tremendous intellectual activity, simultaneous with the exacting duties of a large practice, was the more astounding in that for many years he has been severely handicapped by infirmity and constant suffering. Even while ill, he was ever busy, carrying on many times on nothing but sheer courage. As a friend he was gold thrice refined. His loyalty, thoughtfulness, devotedness, tenderness were the flowerings of a fine spirit. A tribute of love and admiration to Frank Smithies is inadequate without mention of the lovely wife who for twenty-eight years helped and inspired him. To her and his lovely children we bring our sympathy and affection. May the esteem and love paid their husband and father by countless friends and patients help to solace their grief and soften the pain of his absence. Dr. Frank Smithies will live as long as friendship and gratitude blossom on this earth.

Thomas M. Joyce, Portland, Oregon.

In all my relations with him I was deeply impressed with his sincerity, his intellectual integrity and sound, well balanced judgement. Though chiefly concerned in the cultivation and development of his specialty—Gastro-enterology—he had a broad, panoramic view of medicine as attested by his early contributions and researches on goitre and in other fields. His enthusiasm and inexhaustible energy gave him a great capacity for productive laboratory and clinical research which found literary expression in the constant stream of publications that issued from his fertile pen, and in the numerous addresses and lectures which he delivered as a teacher and authority in his special field, much in demand all over the country. His bibliography will suffice to attest to his scholarship, to his

industry and to his devotion to the specialty which he so materially advanced and helped to elevate by his example and spirited leadership.

Rudolph Matas, New Orleans, La.

Medical science has met with a great loss in the passing away of Dr. Smithies and we who knew him personally are filled with sorrow.

Chevalier Jackson, Philadelphia, Pa.

The sudden death of Frank Smithies proved a tremendous shock to his French Colleagues, for we did not know of his illness, so unfailing had been his literary and scientific activities during the past months. Devotion of mind and heart to scientific advancement, industry, intellectual probity, executive power, yearning for scientific truth; his efforts to promote a better *entente cordiale* among physicians of all nations, and particularly between Americans and Frenchmen—these qualities and activities mark him out, in my opinion, as a truly great American physician.

As a student in 1921, and during subsequent clinical tours of England, France and Germany, Smithies' works on cancer, ulcer and nutrition are among the accepted things our masters quoted and desired us to translate. As secretary to Major-General Gouachon, and while on a tour of Hospital Investigation, I was thrown with Frank Smithies daily during a week or more in Chicago, and had the opportunity of gaining his ideas on medical interchanges with Europe. These ideas proved of value when I returned to France. His work as American representative of the "Association for Developing Medical Relations between American and French Physicians," has already borne excellent fruit. He saw the desirability of a closer relationship between the English and French medical institutions in Montreal. We in Quebec Province salute the Departed as a great man, who understood our problems and will always remember his brilliance, his sense of humor and his excellent judgment.

Jean LeSage, Montreal, Canada.

Frank Smithies possessed a dynamic personality; he could never be neutral; nor could he be indifferent; he carried his sovereignty beneath his own hat; his was a virile personality. It is interesting to note that his enthusiasms were always of a constructive trend; his ambition was to build; he spent his energy in constructive activities; he thrived in an atmosphere of flux, but always creative; he revealed in growth, whether orderly or riotous. Essentially an extrovert, yet he was of studious habit; an accomplished salesman, yet, withal of scientific bent; conscious of the power of propaganda, yet he worshipped in the Temple of Fact; a strange mixture of the pedantic and pragmatic. His most outstanding work, aside from making his mind a well-stocked granary, was the American College of Physicians. That organization is peculiarly the result of his labor; he kept it alive in spite of criticism and opposition that was, in essence, personal; he nursed it as a fledgling through the period of the World War; while it did not remarkably grow numerically under his guidance, it did acquire a hardihood that defied the ailments of childhood and permitted it to achieve maturity under the guidance of Stengel. As one who revolted under his leadership it affords an undisguised satisfaction to accord, thus, to Frank Smithies the credit for making an organization place for internal medicine. A brave heart, an unflinching spirit, an able leader and a great physician is gone. He had little peace in life; may he have it in abundance in death.

Virgil E. Simpson, Louisville, Ky.

It is with a sense of personal loss as well as of a distinct loss to Dr. Frank Smithies' many and varied interests in medicine that I learn of his death.

I came to know Dr. Smithies through several avenues. He was one of the profession's indefatigable workers, a man of great energy and ambition, an organizer of wide interests, a leader in progressive and aggressive medicine, a physician of forward vision and keen ability. His death will be felt beyond the immediate interests of our Journal. His energy will not be commonly found among us.

Kenneth M. Lynch, Charleston, S. C.

To me one of the most characteristic traits of Dr. Smithies was his intense, and still lovable, loyalty to those whom he looked upon as his friends. An absence of years made no difference with him. One picked up the thread of his relationship with Dr. Smithies where it had been interrupted as though it had never been severed at all, without any feeling on either's part of change incident to time and absence. Such a trait is born in a man; it can neither be developed nor submerged. And fortunate is he who possesses it, for it compels in return spontaneous loyalty on the part of others. In so intense, so pioneering a life, as Dr. Smithies lived, it doubtless smoothed out many trials and adversities that necessarily came to him. In his passing he has left his imprint on American Medicine to a degree a few only have equaled.

Noble Wiley Jones, Portland, Oregon.

The passing of Frank Smithies has left a gaping void in American medicine. The loss that scores of patients of his have sustained is small by comparison to that which we have sustained. He was the inspirational genius of "our Journal." It was only through his dynamic leadership that the unity of effort was achieved. His was the gift of inspiring the individual to greater efforts and of molding groups of soloists into an harmonious ensemble.

The Leader is gone but that indominatable spirit will always remain with us and we will fulfill our obligation to the great purposes of his life—and carry on.

Martin G. Vorhaus, New York, N. Y.

American Medicine has sustained a distinct loss in the passing of Frank Smithies. An enthusiastic, unbiased investigator, a thorough, kindly teacher, a clinician of the first rank, his publications were known and quoted througout the world of medicine, his methods of diagnosis and treatment were recommended in leading text-books. As co-founder and Editor-in-chief of the American Journal of Digestive Diseases and Nutrition he made a monument for himself which, with the impetus given by his three years of indefatigable labor, should remain a permanent memorial. Organized medicine long since recognized the worth of this remarkable man and heaped upon him, in his all-too-brief career, honors which but few great men have attained in a much longer lifetime. He enjoyed a full life, worshiped by his family, loved by his many friends, and his passing leaves a void which will be difficult to fill.

A. R. Andresen, Brooklyn, N. Y.

The name of Dr. Frank Smithies was known wherever scientific medicine was practiced. Dr. Smithies, throughout his lifetime, was a devout and indefatigable worker for medical progress. His deep interest in the gastrointestinal phase of medicine has been responsible directly or indirectly for many advancements in this field of work. A measuring stick of the scope of Dr. Smithies' interests, his versatility, and his achievements may be seen in his work as Editor-in-chief of the American Journal of Digestive Diseases and Nutrition. A personal friend, a friend of medicine, and an outstanding figure in the medical profession has been removed by the death of Dr. Smithies.

Francis D. Murphy, Milwaukee, Wis.

Dr. Frank Smithies always impressed me as an outstanding forceful personality in the medical world. His numerous and valuable contributions to the literature were lucid and logical and were supported by a wealth of clinical experience. He demonstrated his genius as a leader and organizer in several medical associations and especi-

Life passes, we go, others come and fill the ranks. The filling of the ranks, however, is not a mere automatic, mechanical procedure. There are foot-prints left behind which are often inerasable and which point the way to the newcomers. It is these footprints which lead to a certain goal; this is all that we can leave behind, footprints pointing the way. In the case of Dr. Smithies, our beloved friend, there were left clear footprints indeed. His inexhaustible energy, his jovial nature, his inspiration to others are the things which will always stand out in the minds of those of us who had the privilege to know him. May his foot-steps ever stand out and remind us to follow the way which he all through his energetic life has pointed out.

Henry J. John, Cleveland, Ohio.

The shock occasioned by Dr. Smithies sudden passing is too great for us to properly evaluate his contribution to medicine.

As a young man, he said, "You fellows can play golf and have other hobbies, but mine is writing."

His mind was essentially creative in character. He sat at his desk and planned the organization of the American College of Physicians and carried it through almost single handed. Our Journal is in no small part a creation of his genius, and we link its success with his untiring energy and enthusiasm. It is a fitting monument to his memory.

Horace W. Soper, St. Louis, Mo.

In the death of Frank Smithies, Gastro-enterology has lost one of its valuable and enthusiastic disciples. He was a clinician who thoroughly understood the fundamental science of his art. His letters and words of encouragement have stimulated numerous young investigators in the science of digestion. He worked unceasingly for the advancement of his specialty in our country. He supported and originated many worthwhile efforts to promulgate the better fortunes of his chosen field, with the advancement of which his name is inextricably interwoven. To him the laurels of accomplishment are due and those who know his good works mourn his passing.

A. C. Ivy, Chicago, Ill.

I knew our late lamented Dr. Frank Smithies for many years, and held him in affectionate regard.

His alert mind and keen intellect were always felt and appreciated. He had an outstanding capacity for work and statistical classification. His writings were trenchant, and full of snap and vigor.

As a man, he displayed a charming personality and a most entertaining contact. As a physician, he showed deep knowledge of human nature and of disease. His mind covered with celerity the many angles of clinical studies of the sick. He showed wisdom and resourcefulness in diagnosis and therapy. As a companion, he was witty, affable, and humorous. As a friend, he was affectionate, helpful and unselfish.

He will be greatly missed by members of the medical profession, and his memory will have a lasting place among them.

Allen A. Jones, Buffalo, N. Y.

It has been my privilege to have known Frank Smithies for a quarter of a century, at first merely as a colleague and subsequently as a greatly esteemed friend. I find myself—like many others—mourning his death in a very personal sense. Smithies possessed a strong personality, a determined will and a tireless energy that was all the more remarkable because of physical handicaps. As is common to many strong characters Smithies made some enemies and his convictions sired many critics. I have come to realize, as the years have passed, that most of his critics were over-captious and some of his enemies were far lesser men—even as I—if they ultimately failed to find the amazing good in the man they one time disliked.

As a well rounded clinician and particularly in regard to his special interest in gastro-enterology, as a sub-division of internal medicine, Dr. Smithies climbed well up the ladder and would have gone even further had his Kismet allowed him larger opportunities to develop his natural skill in clinical research.

I keenly recall my first impression of the man some twenty-five years ago when he rose as a floor discussor of a symposium on some gastro-intestinal topic at a meeting of The American Medical Association. The principal speakers were then men of national reputation and Smithies was relatively unknown. Always an able speaker on his feet, and on this occasion reinforced by data of several hundred cases of the topic under discussion, his remarks were direct and to the point and created disquietude on the part of the symposium principals in their efforts to suitable reply. On returning to his chair—next to mine—he handed me the ledger containing the data set down in his meticulously careful way—the data running into several hundred thousand items which he had abstracted and condensed to a ten minute time limit. This was my first impression of Frank Smithies and it gave a significant insight into the painstaking detail-collecting metier that was characteristic of him.

He was literally an indefatigable worker and I believe an honest searcher after the medical truth. I imagine that this may explain his penchant as a "debunker." Smithies had faults—who has not—that created misunderstanding and made his critics race to counter attack. In some respects he was intolerant of the views of others but tempered by a proper and wholesome intolerance of sloppily done investigative work by which the investigator arrived at premature or unsound conclusions.

Dr. Smithies' personal contributions to medicine, and to gastro-intestinal medicine in particular were too numerous to mention—most of them were timely as regards topics of the period, some could be appraised as ahead of his day and a few were so brilliant in their conception that they may prove to be contributions of lasting value to medicine. Among the most interesting were his views regarding the etiology and the life history of peptic ulcer, a subject which was always one of his "pets."

As an organizer and executive leader he was most able. The record of his career as set out in the editorial by Dr. Clement R. Jones amply attests this ability. His leadership—together with others—in rescuing the American College of Physicians when it was sinking into merited oblivion and helping to build it up to its greatly improved present position and a secure future, will remain as a monument to his having lived. Likewise, his efforts regarding the welfare and progress of the American Gastro-Enterological Association and particularly his Editorship of the American Journal of Digestive Diseases and Nutrition, under handicaps physically and economically that would have appalled a less courageous man, can be counted as real achievements.

He was the kind of man who could look adversity in the face and keep on smiling and it can truly be said that he died with his boots on. Such men are not easily missed or their places readily filled.

B. B. Vincent Lyon, Philadelphia, Pa.

In the passing of Dr. Frank Smithies the profession has lost an unusually able clinician and the community is deprived of a man of many parts, a skilled administrator and organizer, and this Journal has lost the distinctive genius of a devoted Editor-in-Chief.

Dr. Smithies will be missed by very many friends for he had a genius of attracting to himself loyal and devoted adherants to whatever cause he was interested in.

C. T. Martin, Montreal, Can.

Doctor Frank Smithies was one of the pioneers in this country in developing an interest in tropical medicine and human parasitology. At a time when few practitioners of medicine were familiar with parasitic diseases, Doctor

I felt that I could always approach Dr. Smithies at any time for his counsel. His ability to study carefully and evaluate a particular case was surpassed by none, and in the treatment of a case he was always careful to see that the younger men with him got to examine a patient and profit by his experience.

Alton Ochsner, New Orleans, La.

It was with great surprise and sorrow that I noted the passing of Dr. Frank Smithies on February 9, 1937. I have been personally acquainted with Dr. Smithies for many years and always regarded him as one of my best friends. During this time, Dr. Smithies has been one of the foremost clinicians in the United States and contributed much to our knowledge of clinical medicine. It is with a sense of distinct personal loss that I am writing this, for, through all the years, our association was most pleasant. Aside from his professional standing and ability, Dr. Smithies' kind heart endeared him to all of his associates and friends.

Charles F. Craig, New Orleans, La.

Frank Smithies stood for energy, enterprise and hard work. At the meetings of the American Gastro-Enterological Association we looked to him for keen and critical discussion of any paper, and, at times, with his "satirical diatribes," as Dr. Pilcher called them, and his profound knowledge of the subject, he tread heavily on the toes of some of the contributors. But he wanted the truth brought out and his criticisms were not personal. In the reorganization of this Association he was an important instrument. During my presidency he was secretary, and though confined to the hospital with a long siege of illness, carried on the needed activities and arranged a program of a quality that up to that time had not been approached. His artistic sense showed in his hobby for old ship models. As Editor of the Journal he consulted all of us on the Editorial Board, and repeatedly sought advice and suggestions from one or the other.

Walter A. Bastedo, New York City.

The passing of Doctor Frank Smithies is a tremendous loss to American medicine. The public has lost one of the leading physicians in this country, and the profession has lost a dynamic personality, a powerful leader and a great teacher.

E. Perry McCullagh, Cleveland, Ohio.

It is with a feeling of personal loss that I learn of the death of Dr. Frank Smithies. An acquaintance which began thirty years ago when Dr. Smithies and I were both living in Ann Arbor has become more intimate within the last few years, since the organization of the American Journal of Digestive Diseases and Nutrition, and has enabled me to see and admire the surprising energy which Dr. Smithies has put into all of his medical work. That others have been impressed by his ability and by this same driving energy is amply demonstrated in the honors which have come to him which have included the Presidency of the American Therapeutic Society, of The American Society of Tropical Medicine, of The American College of Physicians, The American Gastro-enterological Association, assignments of honor as well as responsibility on the Scientific Assembly of the American Medical Association, and the Ribbon of the Legion of Honor of France. Gastroenterology, and medicine as a whole, have lost a man of achievement.

Warren T. Vaughan, Richmond, Virginia.

America has indeed lost one of its distinguished physicians and experimental medicine one of its most enthusiastic advocates. Dr. Smithies had many admirable qualities but in my estimation one of the most outstanding was his unfailing interest in and courtesy toward young men who showed promise of research ability. He was always interested in people who did things and as his whole life was one of accomplishment he indeed served as an inspiration to those who are trying to do worth while things.

Edward J. Van Liere, Morgantown, W. Va.

Ever since my association with the American Journal of Digestive Diseases and Nutrition, I have been impressed by Dr. Smithies' high sense of duty to his position as Editor. He was most energetic in fulfilling his duties as Editor-in-chief and in my correspondence with him, his frankness and earnestness made a great impression.

Howard F. Root, Boston, Mass.

It was with the utmost sorrow that I learned of the sudden death of Frank Smithies. From the time of my first acquaintance with him at the University of Michigan, his life, struggles and accomplishments have always been an incentive to more appreciation and effort on my part. We shall miss his judgment at our councils, his constructive criticisms, his cordiality and his virile will to progress. I wish there could be more like him to whom we might look for advice and stimulation in this chaotic world in which we live.

James T. Pilcher, Brooklyn, N. Y.

In the death of Doctor Frank Smithies, American medicine has lost one of its outstanding personalities. Physically handicapped but mentally alert, Doctor Smithies was a great organizer, a thoroughly trained internist, an excellent writer and a true friend. I am sure that I voice the sentiments of all those interested in the advancement of knowledge pertaining to the gastro-intestinal tract when I say that we have lost a champion who will not be easily replaced.

Porter P. Vinson, Richmond, Va.

The standing and ability of Dr. Frank Smithies in the medical profession are widely known and appreciated and his death constitutes an almost irreparable loss not only to the clientele whom he served but also to those who have long profited by his written communications on medical topics. No others, however, will feel his loss so keenly as his host of friends who knew and loved his personality. Something is gone out of their lives that will not soon be replaced.

William Fitch Cheney, San Francisco.

Frank Smithies has been one of the leading men in digestive diseases for more than a generation. He was a tireless worker, a great organizer, and ever since his early days at the Mayo Clinic has stimulated and carried on an immense amount of valuable clinical research. His genial personality, native talent, and immense experience won him a host of friends all over the country and made him a leading consultant in his special field. This Journal owes its steady progress and leading position largely to his devotion and tireless efforts as Editor-in-chief. His heroic attitude in the face of long disability and finally of serious illness has been an inspiration to us all. He will long be remembered not only for his scientific skill and vast clinical experience, but for his great courage and kindness of heart.

Franklin W. White, Boston, Mass.

Many years ago when I became a member of the American Gastro-Enterological Association, I had the good fortune to meet Dr. Frank Smithies. He impressed me as a man of high, intellectual attainments, deeply interested in his work. While fearlessly critical he was always fair and just. Once you had obtained his support, he was unfailing in his interest and loyalty. We all know how devoted he was to his work with the American Journal of Digestive Diseases and Nutrition.

He will be sadly missed; and will always remain in our memory as a distinguished figure among his colleagues.

Jerome M. Lynch, New York, N. Y.

reff upon the basis that the small intestine could not tolerate and would not accept an acid stronger than from 0.1 to 0.15% HCl. While, undoubtedly, regurgitation of duodenal contents plays probably the most important role in the neutralization mechanism, one cannot escape proper evaluation of the work of Shay, Katz and Schloss (10) who have shown that regurgitation from the duodenum is even greater when alkalis (1-1½% $NaHCO_3$) are introduced into the stomach than when either weak or strong acids are used. We have frequently noticed that the greatest amount of regurgitation occurs in patients with achylia gastrica during a plain water meal. Furthermore, we have been unable to change the color of bromsulphthalein with the regurgitated duodenal contents, even in the presence of achylia gastrica, although this dye changes color at a pH of 7.2. Therefore, it is doubtful if the duodenal content is sufficiently alkaline to *markedly lower gastric acidity even in the presence of* considerable regurgitation. Reference to Figure 2, Graph II, reveals an increased neutralizing power in the presence of marked pyloric obstruction in both cases where duodenal regurgitation is inhibited. McCann (*Am. Jour. Physiol.*, 89:483, 1929) utilizing the Mann-Williamson operation which shunts all duodenal contents into the terminal ileum and short circuits the gastric contents into the upper jejunum, found that the neutralizing power of the stomach remained the same before and after operation. Since Hill and coworkers (*Am. Jour. Physiol.*, 106:381, 1933), using isolated pyloric pouches, have shown that the secreted mucus is neither sufficient in amount or alkalinity to account for the acid reduction, we must give considerable attention to the possibility of resorption or diffusion of hydrogen ions through the stomach itself or that the stomach is actually capable of secreting an alkaline juice as advocated by Author.

That dilution plays some part in the mechanism is indicated by adding a coloring matter (sodium salt of phenolsulphonphthalein) to the acid test meal and determining its concentration in the fractional specimens by means of a colorimeter. The strength of the acid in the meal and fractional samples was determined by chemical analysis and not by titration. It was found that from 55 to 60 per cent of the reduction was due to dilution and 45 to 50 per cent due to neutralization. Both clinical and experimental recent reports tend to show that the emptying time of the stomach plays very little if any role.

The work of Elman and McLeod and of Levy in connection with ulcer and pylorospasm has been confirmed. Since the neutralizing power in the other diseases studied was within normal variations with the exception of liver and gall bladder disease, it would appear that its diagnostic value in ulcer is even greater and more specific than has been previously emphasized.

A modified technique has been introduced which is less difficult of application by the individual clinician who must refer his cases to a laboratory for analysis since by this technique both the secretory and neutralizing curves can be determined at a single sitting. Total volumes of the test solutions have been reduced which has eliminated discomfort and frequent vomiting both of which are aggravating factors to accuracy of the tests.

CONCLUSIONS

1. The clinical value of the neutralizing functional test of the stomach in ulcer and pyloric spasm as established by other investigators has been confirmed. It apparently is of little or no value in other gastrointestinal and several general diseases investigated in this study except the possibility of liver and gall bladder pathology.

2. By modifying the technique of Elman and Levy both the neutralizing and secretory tests can be accurately performed at one appearance of the patient.

3. Evidence is submitted suggesting that the regurgitation of duodenal juices, while undoubtedly the main factor, is not the only one in the mechanism of neutralization.

The Acidity Reduction Test Versus the Fractional Test Meal*

By

FRANK L. APPERLY, M.A., M.D., D.Sc.

RICHMOND, VIRGINIA

THERE is now abundant evidence that the rate at which acid in the stomach is diluted and neutralized is a much clearer indication of gastric function in health and in dyspepsia than is the degree of acidity alone. The reasons for this will be discussed later.

In 1914 Boldyreff (8) first showed that when acid is placed in a dog's stomach the acidity is rapidly reduced. (Fig. 1). This fact was not, so far as I am aware, applied to the investigation of the human stomach until 1923, when I showed that there was a

Smithies called attention to their importance and applied modern methods of diagnosis and treatment in his practice. For many years he took an active interest in the American Society of Tropical Medicine and was elected president in 1931. He also contributed generously to the support of the Society by special donations. As the finest type of gentleman and as a genial, big-hearted friend Doctor Smithies will always have an honored place in the memory of his colleagues.

Henry E. Meleney, Nashville, Tenn.

The death of Dr. Frank Smithies has removed from American gastro-enterology one of the most inspired and inspiring figures. The presence of Doctor Smithies at a medical meeting was always an insurance that there would be a complete discussion of all correlated work, Doctor Smithies' knowledge of medical literature being most extensive, and also that no unsound doctrine would escape keen and complete analysis.

He was wont to say that his physical handicap gave him greater opportunity and desire to study, and this fact redounded to the advantage of all who had professional and social contact with him.

The American Journal of Digestive Diseases and Nutrition, his long cherished dream, is now a most fitting memorial to him, and no greater future for the Journal can be desired than that the spirit of Doctor Smithies live on for many years in its pages.

Sara M. Jordan, Boston, Mass.

The great loss sustained in the sudden passing of Dr. Frank Smithies will be sorely felt both by clinicians, particularly the gastro-enterologists, and by experimental investigators. Dr. Smithies' outlook on medicine was broad; he fully realized the important part which the fundamental sciences play in the progress of medicine and he kept in permanent touch with them, as witness the so-called "Smithies gastric ulcer diet," based on physiological principles. He himself called this the "physiological rest method" (cf. *Amer. Jour. Med. Sci.*, 153, p. 547, 1917) and denounced the method of alkali therapy long before any experimental evidence was obtained that alkali stimulates gastric secretion. That Dr. Smithies was a "physiologically minded" clinician was clear from the general editorial policy pursued by him as Editor-in-chief of the *American Journal of Digestive Diseases and Nutrition*. His aim was to combine within one journal all that was theoretically or practically important in the field of gastro-enterology. Once when submitting to him a purely physiological article, I expressed the doubt that perhaps such an article would be unsuitable for a medical publication. He replied as follows (on 3rd Dec., 1934): "I, personally, and everybody with whom I have talked, appreciate your sending original articles to this publication. I know that a lot of them could have been printed in other journals but then the practitioner probably would not have read them. As a sort of slogan for our publication we have adopted in our propaganda announcements the phrase 'The Magazine Where Investigators And Practitioners Meet.' This slogan expresses exactly what I had in mind when this Journal was started. . ."

Therefore by the death of Dr. Smithies not only is the medical profession deprived of one of its most prominent members, but the theoretical sciences have lost a friend who appreciated their importance and recognized their true value in relation to practical medicine.

B. P. Babkin, Montreal, Canada.

I met Dr. Frank Smithies for the first time at the Mayo Clinic when attending the meeting of the American College of Physicians, in 1922. I took a great liking to this perfect gentleman who was then Secretary-General to the College, and I admired very much his courtesy.

I wrote him on several occasions, since 1931 particularly, after a trip to Paris, with the purpose of organizing annual English clinical courses in the French Hospitals, which were to be given under the auspices of l' "Association pour le Développement des Relations Médicales entre la France et les Pays Amis" (A.D.R.M.) founded by Professor Henry Hartmann, and president ever since by this well-known Parisian surgeon.

On my return to Montreal I thought that Dr. Smithies was one of the many American physicians who could tell me whether such a similar organization would meet general approval in the United States. Dr. Smithies' answer contained such appropriate advices on the matter that I sent copies of his letter to Professors H. Hartmann, E. Sergent, G. Roussy and some other of my friends members of l'A.D.R.M. in Paris. All eminent medical authorities of Paris and France got acquainted since with Dr. Frank Smithies whom they admired for his "Franc parler" and generous contribution towards the English clinical lectures in Paris. I personally know that Dr. Smithies has been constantly in correspondence with his French confrères up to his death.

I had, about that time, founded in Montreal the Canadian section of l'A.D.R.M. with the cooperation of Dean A. Primrose of Toronto University, C. F. Martin, Dean of McGill University, Louis de Lotbiniére-Harwood, Dean of l'Université de Montréal, A Rousseau, Dean of Laval University, Quebec, and many other colleagues. The following year Dr. Smithies organized the American section of l'A.D.R.M. with the collaboration of Drs. James R. Arneill, Lewellys F. Barker, Harlow Brooks, George Crile, Maj. Gen. Hugh Cumming, A. U. Desjardins, George Dock, Reginald Fitz, Maj. Gen. M. W. Ireland, N. W. Jones, W. McKim Marriott, Martin E. Rehfuss, William J. Mayo, J. H. Musser, Carl V. Weller and others.

It was through the requests of Professors H. Hartmann, E. Sergent G. Roussy, E. Rist and other members of l'A.D.R.M. in Paris, jointly with the French Council in Chicago, that *la République Francaise* bestowed on Dr. Smithies the decoration of Chevalier de la Légion d'Honneur. I personally know that he heartly appreciated this delicate attention of his Parisian friends and that he was proud of the little red ribbon he constantly wore.

I must say that it was in 1933 that I had the second opportunity to meet Dr. Frank Smithies when he came to Montreal to attend the first Canadian session of the American College of Physicians. I hope every Fellow of the College who was present still believes it was a particularly interesting meeting, because they had the opportunity to see in our City two medical schools: one of McGill University and the other of l'Université de Montréal, having both their personality and traditions. McGill has always been known as a prototype of the English Universities, while l'Université de Montréal takes its own inspiration in its French ascendants, the Universities of France. Montreal is a living example of the "good entente" existing between its citizens of French and English origins. Dr. Smithies and his colleagues were then interested in both medical schools and their respective teaching hospitals where they attended clinics during this memorable meeting of the College.

Dr. Smithies and many other Fellows were welcomed in the Hotel-Dieu, Notre Dame, Ste-Justine and other French speaking hospitals where they delivered special clinics. I remember how pleased Dr. Smithies was after meeting Prof. Pierre Masson, previously of Strasbourg University, France, in his laboratory where he had with him a long talk on the pathology of cancer of the stomach. Prof. Pierre Masson was also very much interested with Dr. Smithies' remarks on pathology.

It was through Dr. Smithies together with Dean C. F. Martin and Prof. J. C. Meakins of McGill, that the College invited Prof. E. Rist, the well known specialist on tuberculosis, of Paris, to attend this Canadian meeting of the College. I am sure all the members of the American College of Physicians who were then in Montreal

remember the great success of Prof. Rist in his clinical lectures at Notre-Dame Hospital and at the general meetings at the Windsor Hotel, specially on account of his clinical science and his perfect knowledge of the English language.

It was my privilege on the same occasion, as President of the Canadian section of l'A.D.R.M. to entertain at a luncheon, at Le Cercle Universitaire, in honor of Dr. Frank Smithies, President of the American section of l'A.D.R.M., and Prof. E. Rist, member and delegate of l'A.D.R.M. in Paris. Some of the most prominent members of the American College of Physicians and representatives of McGill and l'Université de Montréal, as well as the French Consul in Montreal, and two Hon. Ministers of the Quebec Government were present.

The medical profession of the United States has suffered a great loss by the premature death of one of its most representative members. Dr. Smithies' numerous admirers in Paris have, I am sure, learned with deep sorrow of the sudden departure of their grand American friend and colleague.

Dr. Smithies' close friends and collaborators will appreciate his numerous contributions to medicine and his everlasting enthusiasm in the organization of the American College of Physicians and his work on the "American Journal of Digestive Diseases and Nutrition" in which he was so kind to associate some of his French Canadian friends of Montreal.

I am very proud to have been called upon to say a few words on this remarkable physician who will remain as a living example of an indefatigable worker, an honest man and a most devoted friend. It is on the tomb stone of such men that one may engrave: "HIC JACET VIR PROBUS."

J. E. Dubé, Chevalier de la Légion d'Honneur,
Montreal, Canada.

After I came into this country two and one-half years ago, I met Doctor Smithies on several occasions, none of these meetings lasting less than two hours, and I always left the room with a strange feeling of surprise and admiration. I felt his appreciation of "humanistic education" (I think this is an adequate translation of the German "Humanistische Bildung"), which evidently he had had in largest extent. I felt his ability to follow and to appreciate new ideas. I have considered him as one of the most perfect gentlemen I ever met. I always left him not only encouraged, but enthusiastic, full of confidence in the future of my own ideas, because he seemed to share them. That he was able to show me this confidence, proves that he not only was a gentleman but that he also was full of that natural friendliness which makes the great physician, which is inborn and can never be acquired. How will it be possible to replace him as Editor-in-chief of the American Journal of Digestive Diseases and Nutrition which was raised in two years to the leading periodical of its kind in the international scientific world? His successor will have a hard task; but we, his collaborators, should promise whoever he may be, to support him by all means to honor the memory and the work of unforgettable Dr. Frank Smithies.

Rudolf Schindler, Chicago, Illinois.

My intimate acquaintance with the late Frank Smithies began in the summer of 1933, when I called at his office for an informal chat and discussion of matters gastroenterological. I had known him professionally for a number of years and we had a few medical cases in common. I had always been impressed with the thoroughness of his clinical work. He had a flare for sizing up the psychological as well as the physical status of his patient. His patients were bound to him always by so strong a bond of confidence, that it was nearly impossible for another physician to fill his place even temporarily. He exacted and obtained from most of his patients a degree of regimentation, where it was necessary, such as I had never before seen or believed possible. He devoted a good deal of time to what at first often seemed insignificant phases of the illness. He had a distinct clinical instinct for diagnosis and used X-ray and other laboratory aids as mere secondary guides. His letters to physicians reporting on referred cases were exhaustive, and his instructions to patients were extremely detailed.

I called on him in August, 1933, to ask his opinion as to the advisability of starting a Journal in gastro-enterology and explained to him that this idea had been in my mind for a number of years. He gave me a quizzical, penetrating glance and asked, "why in h—— should you want to do that?" I confessed that my motives were as strong as they may have appeared ill-timed. The depression was then obtrusively present. I assured him, however, that I could interest publishers, and this fact obviously surprised him. Immediately, he decided to take the matter seriously, and it was not more than two weeks before he had assembled the Editorial Council, while I in the mean time made financial and printing arrangements.

During the four years that have passed, we worked in close harmony. Dr. Smithies was self-sacrificing in his work. Last summer, while ill and unable to work, he maintained touch with my office at all times. He even assumed the work of a technical editor, believing that his own personal touch was essential to the undertaking.

It is unanimously admitted today that Frank Smithies, as Editor-in-chief of this Journal, did an excellent piece of pioneering work. He did it thoroughly, with the vigor for which he is famous and he did it cheerfully and consistently. If he had strong dislikes, he also possessed very unusual fidelity to his accepted friends. In his contacts, it may be said, that he left no one cold; for his personality was an unusual blending of prejudice and loyalty. Above all, he was one of those rare men, whose unquenchable enthusiasm burned like a light, emphasizing its brilliance by its own untimely extinction.

Beaumont S. Cornell, Fort Wayne, Ind.

ANNOUNCEMENT

Soon after the death of Dr. Frank Smithies, Editor-in-Chief of this Journal, a slightly different plan of editorial management was decided upon. Following the practice of a number of leading medical journals in America, the position of Editor-in-Chief was abolished and responsibility placed upon a group of men comprising an Editorial Board. The members so far appointed are: Walter C. Alvarez, Rochester, Minnesota; Burrill B. Crohn, New York, N. Y.; Henry L. Bockus, Philadelphia, Pa., and Sara M. Jordan, Boston, Mass. The position of Supervising Editor is still retained by the writer. All manuscripts submitted for publication should be mailed to Dr. Cornell at 116 East Berry Street, Fort Wayne, Indiana. They will be sent at once for review, suggestion, criticism, and acceptance or rejection to appropriate members of the Board and Council. A technical editor will be appointed for such revision of articles as is considered necessary. It is felt that this method of editorial management is appropriate for this particular journal. To readers we may give assurance of a steady inflow of excellent contributions from many sources. To authors, we may state that we are still in the desirable position of offering quick publication. Furthermore, it is felt that suitable and adequate adjustment

has been made; and that the Journal, ably piloted by Frank Smithies through its early years, will continue to progress under the expert guidance of the Board and Council.

Beaumont S. Cornell, Fort Wayne, Ind.

Early in February, Dr. Henry J. John of Cleveland, Ohio, was given the Charles Eisenman Award of the Jewish Welfare Federation for his work in creating and maintaining Camp Ho-Mita-Koda for diabetic children. This work of Dr. John's for youthful diabetics has deservedly received wide recognition for a number of years. He has diverted the $750, which accompanies the award, to the work of the Camp.

NOTICE

The Annual Meeting of the American Gastro-Enterological Association will be held at the Hotel Claridge, Atlantic City, N. J., on Monday and Tuesday, June 7th and 8th, 1937. Please make hotel reservations at once.

Book Reviews

Physiological Chemistry. By J. F. McClendon and C. J. V. Pettibone, sixth edition, C. V. Mosby Co., St. Louis, 1936. 451 pages, 34 illustrations.

THE first section of this text, amounting to 322 pages, is devoted to exposition of the subject matter of physiological chemistry; the remainder (Section II) contains instructions for laboratory exercises. This is the first revision since 1931, the book having been issued originally in 1917. Except for certain subjects, the exposition is elementary and in many respects incomplete. Although the liver is the center of many types of intermediary metabolism with which physiological chemistry is concerned and which is important for the medical student and physician to know, the word "liver" is not mentioned in the index.

In these days of rapidly expanding knowledge in the fields of physiology and biochemistry, the problem of selection of subject matter to be presented to medical students in these subjects is a serious one. In the case of this book it is believed that the authors err in presenting too little of the subject matter of biochemistry, in view of the fact that most students now admitted to medical schools have had courses in organic chemistry and quantitative analysis. They must know considerable biochemistry in order to understand the metabolic disturbances that occur in so many diseases, and to interpret and understand the biochemical methods used to detect functional disturbances.

The book has the merit of simplicity and lucidity. It will serve as a good introduction to the subject of biochemistry, or as a basis upon which to build a more complete and essential knowledge of the subject. It is of little value as a reference source.

A. C. Ivy, Chicago.

Knud Faber: Gastritis and Its Consequences. Oxford University Press, London, etc., 1935. 119 pages, 48 illustrations.

THIS monograph, by Knud Faber, Professor of Internal Medicine in the University of Copenhagen, on gastritis most likely will become one of the classics of gastro-enterology. The author writes: "It is possible that the exposition I have given in these lectures may be considered to have too much of the stamp of my own personal views, which are not shared by all." This certainly is true, and exactly this quality of the small book increases its value immensely. Every page challenges the expert reader, every sentence could be discussed, nothing can be found of the smoothness of a usual textbook containing only ascertained facts. A tremendous experience becomes visible in every line, in fact, the experience of a whole human life. It must not be forgotten that since 1898 Knud Faber has been almost the only clinician to emphasize the existence, frequency and importance of gastritis. Very few workers sustained his opinion, and for 25 years he stood alone continuing his work and his fight. Only with the advent of routine gastroscopy in 1923 and with the work of German pathologists did the situation change. It changed so completely that now gastritis is considered the most frequent gastric disease. Knud Faber's final triumph is a complete one, but his book almost does not mention these events; the modesty of the aged author is remarkable.

The book is composed of three parts corresponding with three lectures delivered at Guy's Hospital Medical School in November, 1934.

In the first part: *"Acute and Chronic Gastritis"* Faber emphasizes the frequency of stomach diseases. Among 120,000 members of the health insurance societies of Denmark, 10%-13% had gastro-intestinal diseases, while only 1.3% had cardiac diseases. Because most of the gastric diseases are not fatal they persist longer and may accompany a patient through a long life. After short historical considerations, Faber describes his famous formalin injection method for preserving the stomach after death. Immediately after death, 500 c.c.m. of formalin solution were injected into the abdomen, and an excellent fixation of the tissue was obtained. Nevertheless, the interpretation of the pictures of the gastric mucosa found microscopically was not easy because dilatation of the stomach and post mortem changes often gave the impression of more advanced atrophy than really existed. Faber then describes the method of Konjetzny, Kalima, Puhl, who examined microscopically freshly resected specimens, but who naturally could examine only the antral part of the stomach. The sudden evolution of gastroscopy in Germany is described and it is stated that those investigators (Schindler, Gutzeit, Henning) claimed that chronic gastritis has been shown to be extremely common.

On one page the description of the normal histology of the stomach is given, chiefly derived from examinations in newborn children. This picture almost never is found in adults, yet Faber seems to be inclined to

call all differences from those in the stomach of the newborn, "gastritis."

An excellent description of acute gastritis is given. Beaumont's famous report on the Canadian St. Martin is quoted extensively. Faber differentiates between "irritation gastritis" and "hematogenous gastritis." The *irritation gastritis*, a very common disease, can apparently be completely cured, but generally leaves behind traces of inflammation. Renewed acute outbreaks finally lead to chronic gastritis. Faber has an extended experience on the *"hematogenous,"* acute gastritis. Numerous observations made in cases of typhoid fever, diphtheria, influenza, pneumonia, etc., illustrated by photographs, are convincing. A thorough description of the microscopic changes is given, but acute *"irritation"* gastritis does not lend itself readily to anatomical investigation, since it is not a fatal disease. In chronic gastritis a combination of acute and chronic processes will be found. Two distinct forms are encountered, namely, "chronic erosive gastritis" and "diffuse pangastritis which tends toward atrophy." It is important that Faber states that chronic erosive gastritis is best known from examination of resected parts of stomachs operated on because a chronic ulcer has been diagnosed, and that diffuse atrophic gastritis is best studied in post mortem specimens. The results obtained with the formalin method in the second form are convincing. The erosive gastritis usually is pyloric gastritis. The microscopic picture is of an acute character, the erosions usually not penetrating through the mucous membrane. However, also chronic changes are found. The mucosa in chronic diffuse *pangastritis is smoothed out, the color is pale, no* erosions are seen, microscopically there is no acute inflammation, plasma cells and lymphocytes predominate, the surface epithelium is unaltered, but the gland epithelium is destroyed, at first in patches, later over an extensive area; the thickness of the mucosa may be reduced to a fraction of its normal depth; cysts often occur; regenerative processes are observed. This hyperplasia may lead to *"gastritis chronica polyposa."* A curious metaplasia of the epithelium into a goblet-cell epithelium is frequent.

The second part of Faber's book is called: *"Gastritis and Hyperacidity."* It contains, however, many observations which have nothing to do with the title. At first Faber emphasizes the importance of gastroscopic observations, admitting that he himself is not an expert in gastroscopy, but stating that all gastroscopists unanimously have maintained that the most important result of gastroscopic investigation is the recognition of the enormous frequency of gastritis. He believes that these observations must be accepted because they agree so accurately with the anatomical findings. Hyperacidity often is found in the initial stage of gastritis. At this point Faber starts a discussion on Hurst's "ingenious hypothesis" on the presence of an inborn gastric "diathesis," a discussion frequently reappearing later. It becomes evident that Faber does not accept Hurst's theory although he admits that in the origin of a disease several factors may play some role. In this review the reasons given extensively by Faber shall be omitted. By comparing the anatomical picture with functional findings he makes the following important statements: "There are grounds for stating that no closer parallel between anatomical lesion and functional disturbances exists. Anacidity is certainly a natural consequence in the severe atrophic forms, but, in the less advanced cases, we cannot estimate the degree of secretory disturbance from the anatomical picture, nor even distinguish between cases where the secretion is diminished and those where it is increased." A return of the hydrochloric acid secretion can be observed in all degrees of reduced secretion.

In the following description of the "pyloric gastritis" Konjetznys findings are quoted. Cases are mentioned in which resection was carried where there had been a diagnosis of chronic ulcer, but in which only gastritis was found; this form of gastritis, which causes more or less typical symptoms of ulcer, must be very common. A lengthy discussion of the clinical picture of this disease follows. Hemorrhage is a frequent symptom. Nearly all of these cases have periodic occult hemorrhage, many produce gross hemorrhage. The mechanism of pain, vomiting, stagnation is discussed. It is important to differentiate between erosive gastritis and ulcer because of the different prognosis. The symptomatology in the whole is vague, but, at all events, the great importance of gastritis as the cause of the clinical pictures of dyspepsia must be regarded as established. Faber admits the theory of Konjetzny, that "the disease which leads to chronic ulcer in the first instance must be a gastritis."

The book's last chapter is that on *"Gastritis and Anacidity."* Faber quotes Bloomfield who flatly refuses to accept the thought of gastritis as a cause of anacidity, but also is unable to acknowledge the existence of constitutional achylia. Faber, however, believes that the main argument in favor of gastritis is that when one microscopically examines the mucous membrane of the stomach after proper fixation, one always finds, in patients with chronic anacidity, a diffuse gastritis, tending to atrophy or to pangastritis. "Once one has seen the great inflammatory changes in the mucous membrane in a case of chronic anacidity, one cannot help coupling them with the cessation of secretion." "But it is not our view by any means that all anacidity is due to gastritis." With this Faber arrives at a consideration, long expected by the reader, of the role of psychic influences on the gastric secretion. They are briefly but sufficiently discussed. Also toxins may cause anacidity without gastritic changes, as for example, in Grave's disease. In beriberi and pellagra alimentary factors may have a similar influence. Anacidity in relation to the different age groups then is discussed, the statistics of Vanzant and Alvarez and of Bloomfield are quoted. In children the acid secretion is easily affected by acute diseases, and this probably is due to acute gastritis. Since chronic gastritis may be the ultimate result it can occur at any age. The fact that anacidity so often does not produce symptoms over a long period of time is compared with the periods devoid of symptoms with ulcers and with the initial stage of cancer. Often the inflammation has become "quiescent." However, it is in the nature of pangastritis that it is always advancing, tending toward the atrophic stage. Then Faber considers the relation between chronic gastritis and pernicious anemia and other forms of anemia. He comes to the conclusion that true pernicious anemia must be regarded as a disease of the pyloric organ with deficient secretion of Castle's antianemic factor. In the same way, chronic gastritis is considered to be the

cause of combined cord degeneration. Finally Faber discusses the possibility of chronic gastritis being the primary factor in the development of gastric cancer. Observations are quoted which make the transition of chronic gastritis into gastric cancer likely. However, the author thinks that there must be a tissue predisposition for the formation of cancer.

In conclusion, Faber states that gastritis is not only an extremely common disease, but a very important one. Apart from its own symptomatology, it bears within itself the possibility of chronic diarrhea, chronic ulcer, pernicious and simple anemia, and perhaps cancer. It is in the early stages that we have a prospect of stopping the development of gastritis, and thereby not only relieving the patients of the transient symptoms, but also preventing the further development of gastritis and its often fatal consequences.

It already has been said that this small and inexpensive book contains the results of 40 years' efforts—results obtained against the resistance of almost the entire scientific medical world. Would it be respectful and wise for the present reviewer to critisize in such an exceptional case? Certainly not as far as the many debatable questions arising on each page are concerned; but perhaps it is his duty, as a reviewer, to point to major objections, just because he considers this work as indispensable for the library of every physician who seriously is interested in internal diseases. Only two such objections can be brought forward: (1) The question of the normal histology of the stomach. We have recorded that the normal histology of the stomach is described on but one page, and is based almost entirely on microscopic examinations of the gastric mucosa of young children; there is not even an illustration of the normal antral mucosa. No adult stomach is supposed to be free from chronic gastritis. If this were so, evidently all consequences would lose much of their value. If the changes seen microscopically in the stomachs of adults are considered, three interpretations seem to be possible: (a) every adult, even the healthiest one, has chronic gastritis; evidently with this statement the term of chronic gastritis would lose again its clinical significance; (b) chronic gastritis does not exist; the respective microscopic changes are normal features: this is not credible; the microscopic pictures of complete atrophy cannot be considered otherwise than the consequences of a chronic disease; (c) some microscopic changes in the gastric mucosa of the adult as compared with the microscopic picture as seen in children are characteristic for a "disease" in the clinical sense of the word, others are the "normal" reaction of the gastric mucosa toward the daily hot, cold, or irritant food, or they are the innocuous remainders of acute gastritis. This conception probably will be accepted, and therefore a new demand is made upon the gastroenterologist, namely the necessity of drawing the line between "normal" and "pathological" and to adjust the microscopic with the clinical picture. This new work must be based chiefly on Faber's research; probably it can be carried out only by comparison of clinical with gastroscopic and histologic pictures. (2) The second objection is less important in the principle. Are the specimens obtained at gastric resection useful material; are they beyond criticism as being representative? Does resection in ulcer stomachs sometimes lead to artefacts? It is known that the severe antrum gastritis, as described by Konjetzny, has been considered as a regional peculiarity (Walters), but this explanation is not very satisfactory. When reading Faber's book, one gets the distinct impression that the author himself trusts more to his wonderful formalin injection method than in the microscopic pictures obtained at resection. In this important question only coöperation between the clinician-gastroscopist and the anatomist will lead to a final solution.

However, it certainly has become evident by this latest discussion of gastritis that Faber's book marks a turning point in the history of this particular phase of gastro-enterology.

Rudolf Schindler, Chicago.

Synopsis of Ano-Rectal Disease. By Louis J. Hirschman, M.D., F.A.C.S. Published by C. V. Mosby Company, St. Louis, Mo., 1936, 288 pages. Price $3.50.

IN the Preface, the Author states that "this volume has been prepared in order to bring before the medical student, as well as the general practitioner, a small condensed work on the diagnosis and treatment of the commoner diseases of the anus and rectum." Persual of the book reveals that Dr. Hirschman not only well has attained his goal but, in addition, he has turned out what the reviewer believes really is a model compendium—a needed type of publication in these days of expensive and all-too-often, discouragingly wordy, major text-books in special fields of endeavor.

As we studied this book, the thought forced itself upon us that a useful and profitable opportunity presented itself to the publisher who would issue a couple of dozen such monographs written by practical experts and who had the facilities to enable him to sell them at the modest price asked for Dr. Hirschman's work. But, each book must need be written, actually by a well-recognized authority and each book must be "organized" as practically and efficiently as is this compendium.

Of course, many of us "oldsters" recognize that in many aspects, real *surgical* proctology in the United States almost is symbolical with the name "Hirschman." More than 30 years ago, he was a pioneer in debunking the "touch and go" type of work which passed for "proctology" and in placing on a plane of diagnostic and surgical legitimacy, organic affections involving the anus, rectum and pelvic colon. The road was not smooth, largely because of the obstacles raised by general surgeons who denied—some die-hards still do!—that special surgical manoeuvres were demanded for successful management of ailments in the prescribed field. Only by years of teaching, preaching, skillfully operating and doggedly sticking to his specialty, has Dr. Hirschman demonstrated his major premises. Today, due in great part to him, American proctology is a dignified and necessary specialty, with its own responsibilities, nomenclature, diagnostic criteria, efficient surgery, pathology and earnest, capable proponents. In three decades, our profession has seen proctology advance from semi-quackery, hap-hazard diagnostic methods—and even more hap-hazard and frequently destructive and crippling surgery—to a specialty without whose practice no clinic or hospital can claim first rank. To a scant dozen men—one of whom is Dr. Hirschman—is our profession indebted for such remarkable progress.

The work which the Doctor now puts forth is not just an abstract of his long-recognized and standard,

exhaustive text-book. It is a new and complete publication, systematically, and in orderly and reliable fashion, detailing in easily-read—and remembered—crisp language, the essentials for the accurate recognition and management of crucially-located disease. As a result of many years of undergraduate teaching and operating in important institutions where well-manned laboratories were available to supplement clinical procedures, Dr. Hirschman is uniquely capable of sifting fact from fancy and making worth-while each paragraph of his book.

Although regarded as but a "compend," the book is by no means just a "question-and-answers" publication. Stript of excess verbiage, in 16 chapters, are discussed authoritatively anatomy, physiology, symptomatology, methods of special examination, anesthesia (for both office and hospital employment) and the majority of the functional and organic affections of anus and rectum which will be met in day-by-day practice. Differential diagnosis, pathology and therapy—medical and surgical—are featured. The entire subject is emphasized and made clearer by as many as 174 black and white illustrations and six colored plates. Many of the Author's instruments, dressings, little "tricks" in technique, etc., are exhibited and in numerous instances, photographic reproductions of the actual steps in, and the end-results of, operative procedures make the treatise particularly lucid and valuable. Certainly, we know of few professional directions in which the physician can invest three and one-half dollars and have returned to him so great dividends. This book demonstrates amazingly what of material value can be given when Author and Publisher work in harmony.

Dr. Hirschman's book is printed in particularly well-selected easily-read type, on sturdy paper which brings out values in the pictures, and is strongly and attractively bound. Nowhere does one get the impression of a "cheap" book, even though the price is placed so low. There are convenient chapter synopses and a more than ordinarily complete index.

Probably the reader of this review has secured the impression that the reviewer is well pleased with the work of Dr. Hirschman and Publisher Mosby. Let us add that he *is*, and he feels confident that if the book is bought and is used regularly by physicians generally, better work will be done, patients will be relieved of annoying ailments and, more than at present, will doctors share in the material rewards said to be available by the "prosperity" which trained economists tell us now is inundating the entire land!

Frank Smithies, Chicago.

Marcelo Royer: *Higado y páncreas.* Buenos Aires, 1936.

ROYER has written a very convenient and well illustrated booklet of 132 pages on the liver, bile ducts and pancreas. It is part of a "System of Semeiology." Most of the book is taken up with a discussion of the methods of examination of the liver and bile ducts. I fear that some of the descriptions of these technics are too short to be of service either to a student or to a practicing physician. There is a well illustrated section on the roentgen-ray diagnosis of gall stones. The only criticism I feel like offering in regard to the book is that the author should have had more space in which to go into details. He did remarkably well with the space that he had, but there are many subjects which cannot be treated adequately in a few pages no matter how great the skill of the writer.

Walter C. Alvarez, Rochester, Minn.

Annual Abstracts of Proctologic Literature, 1935-1937

By CHARLES E. POPE, M.D., Evanston, Illinois

PRURITUS

ETIOLOGY AND DIAGNOSIS

Hermance and *Bacon* review all phases of pruritus ani in the Cyclopedia of Medicine.

Zweig believes rectal bleeding comes from ulcerous sphincteric proctitis resulting many times in anal pruritus and eczema. Uses subcutaneous injections of plenocain.

TREATMENT

Cotté reports a refractory case of anogenital pruritus cured by presacral nerve resection and isophenolization of the hypogastric periarterial plexus.

Delherm and *Fainsilber* advocate diathermy in the treatment of pruritus.

Gonzales reports 3 cases of anovulvar pruritus cured by the use of ergotamine tartrate used to provoke a regional vasoconstriction, consequent cessation of vascular serous transudate and edema, and nerve irritation.

Ketron and *Ellis* cite cases and describe the histologic changes in Kraurosis vulae and white spot scleroderma believing that the leucoplacia may be a secondary inflammatory change superimposed on a degenerative vulvar phenomenon. Of 9 cases mentioned 7 were described from a view point of the vulvar pathology. No mention of possible rectal source or relationship was made although the principal case was described as being of marked anal involvement.

Maeth advises the use of anucaine in the treatment of pruritus and fissure. Uses 10 c.c. in 5 c.c. anterior and posterior quadrant injections.

Sulzberger and *Wolf* divide pruritus into idiopathic and secondary types. Advises autohemotherapy, ultra violet radiation and unfiltered X-ray suberythema doses.

Upham reviews the work of others and uses 40% alcohol injections as well as Gabriels solution in the treatment of pruritus.

STRICTURE

Bacon reviews all phases of rectal stricture in the Cyclopedia of Medicine.

de Brito quotes a case of perforation following simple dilatation of the rectum.

Kondoleon reports two cases of hyperplastic rectal stenosis cured by excision of the infiltrated perirectal tissue by coccyx removed and dissection down to the mucosa, followed by bougie dilatation. Temporary colostomy preceded one of the cases.

Lockhart-Mummery and *Davis* describe a new technique for fibrous stricture of the rectum in which a posterior proctotomy combined with lateral dissection to permit mobilization of the rectum was done. The stricture was divided longitudinally and drained.

Bacon, H. E.: Rectal Stricture. The Cyclopedia of Medicine, p. 1116.

TUMORS OF ANUS AND RECTUM

(Also see Special Tumors of Colon, Inflammatory Lesions of Colon, Adenomas and Cancer).

Adenomas — (See under separate heading).

Adenomyoma — (See Bowing under Roentgenology and Radium Therapy).

LIPOMA

Weinstein reports what he states is the twelfth case of rectal lipoma. However, *Comfort* has reported 9 cases. It was located in the posterior rectal wall and measured 7 x 4 cm. being attached by a pedicle 6 cm. in length and was covered by a thin mucosal layer slightly ulcerated. Symptoms were of a 6 months constipation and a one day history of protrusion with some pain and bleeding.

LYMPHOCYTOMA

Billaud et al cite a case where tonsillar lymphocytoma was followed in 2 years by rectal lymphocytoma and was cured by roentgen therapy.

Steindl cites a case apparently similar with circumscript hyperplasia of the lymphoid tissue. Surgery is recommended.

MELANO-EPITHELIOMA AND HEMANGIO-ENDOTHELIOMA

Two cases of each condition are cited by *N. D. Smith* and *Broders*. One of each type was found by routine microscopic examination. A hemangio-endothelioma resembled an external hemorrhoid. 330 mgm. hrs. of radium was used. One case of melano-epithelioma died from metastases 21 months later, in spite of irradiation. Hemangio-endothelioma grow slowly, do not necessarily metastasize and have a much better prognosis than the melano-epithelioma where, however, an early diagnosis may cure.

SARCOMA

Del Valle et al and *Chisholm et al* each report a case of sarcoma of the rectum.

Billaud, Brillouet and Viel, A.: (Four-year Cure After Roentgenotherapy of Pure Rectal Lymphocytoma in Same Patient: Question of Metastatic Nature of Second Tumor). *Arch. d'Electric. Med.*, 43:394, Oct., 1935.

Weinstein, S. D. and Liberman, W.: Lipoma of the Rectum. *Am. J. Surg.*, 29:424, Sept., 1935.

VENEREAL DISEASES OF THE ANUS AND RECTUM

Clements and *Hughes* state that of 160 patients with genitourinary gonorrhea, 69 showed rectal involvement as determined by culture and microscopic examination. Uses 1:5000 acriflavine efficaciously.

Grandclaude and *Tison* in an extensive study of various acute and chronic infections of the rectum discuss diffuse syphilomas, acquired rectal syphilis, gummas, gummatous ulcerations and sclero-gummatous syphilids. The macroscopic appearances are described.

Simon describes two cases of soft chancre of the anus.

Clements, P. A. and Hughes, K. E. A.: Incidence of Proctitis in Gonorrhea of Females. *Lancet*, 2:18, July 6, 1935.
Grandclaude, C. and Tison, P.: (Rectitis: Anatomico-pathologic Study). *Echo Med. du Nord*, 3:614, April 28, 1935.

CARCINOMA

INCIDENCE AND GENERAL FEATURES

Carcinoma will always continue to be of primary concern to us. The incidence of cancer of the colon and rectum is emphasized by *Balfour* who states that of 833 consecutive cases of carcinoma of the alimentary tract seen at the Mayo Clinic, 25.9% were rectal and 10.9% were colonic. Of this same group in comparison, 11.6% were of the esophagus, 50.3% were stomach, and 1.2% small intestine. The resectability of these growths showed 58% of the rectal group resectible, and 50% of the colon resectible. The colon and rectal cases showed 39% with 5 year cures with resection varying from 36% in the rectosigmoid to 51% in the cecum.

Sheeler states the death rate from cancer has increased from 39 per 100,000 in 1900 to 110.8 in 1932 or a 300% increase. Basing his figures on the 1930 report of the American Society for the Control of Cancer he states 5% were rectal cancers.

Partsch reporting on the incidence of cancer in the large bowel that since the report of Nordmann on German Surgeon's day in 1926, experience with their cases show carcinoma is equally distributed in the large bowel—1/3 in the sigmoid, 1/3 in the left colon and transverse colon and 1/3 in the right half of the colon.

Shaw in one of the papers given in a Symposium before the Iowa State Medical Society states that Mallory in a review of 3535 gastro-intestinal malignancies showed 51.54% were of the large bowel.

As to the exact cause of cancer, of course, nothing has been proven. *E. G. Martin* states "Thoughtful consideration should be given the hypothesis that cancer results from an individual susceptibility to an unknown factor which initiates the pathological process. Heredity however is an unproven factor." That it plays a part in particular types of cancer is stated by Craver as being indisputable, although "in general cancer in man does not appear to be influenced by a genetic factor."

Craver reviews the various exciting factors, the host of irritants, chemicals, tar derivatives and the relation of the latter to the hormones and sterils. He quotes Ewing as saying "Man is the only animal that enjoys unlimited access to food and suffers from restricted opportunity to empty the bowel, and he is the only animal that suffers notably from gastric and rectal cancer." Craver states that with the multiplicity of inciting factors it is questionable as to whether some universal growth stimulating substance will be found operative in conjunction with all factors concerned. Further investigation and advancement may be made as the study and treatment of cancer becomes recognized as a specialty.

Rosser reviews 25 cases of anal cancer studied over a ten years' period and shows that of this series 84% were associated with benign lesions, fistulas 11, hemorrhoids 8, polyp 1, and cryptitis 1, showing that the malignant process was at least partially induced by chronic irritation. Buie's incidence of 1.73% of anal malignancy he believes is explained on the basis of the figure being determined by including total sigmoid as well as rectal lesions, and that only squamous-celled neoplasms were so classified.

Bacon confirms the work of Gruskin which would strongly indicate a genetic factor in the cause of cancer, and advocates this intradermal test as a routine diagnostic measure.

PATHOGENESIS

Junghanns in a study of 130 operative specimens of the colon and rectum states that 70% showed an unquestionable relationship to intestinal polyps. Of those which developed from polyps only 27 belonged to the villous group. These were benign, precancerous or definitely malignant. Epithelial changes occurred in the middle and were fol-

lowed by an ulcer with a hard base when definitely malignant.

Probably one of the most important papers on the pathogenesis of cancer of the rectum is that of *Gabriel, Dukes* and *Bussey* who studied the lymphatic spread by a special method of dissection to determine which cases are of regional lymphatic spread and in which the extension carried up to the point of ligature of the blood vessels. If the latter occurred, extension is usually superior to this point. If a lateral or downward spread occurred, it was a late affair due to hemorrhoidal lymphatic blockage. The lymphatic spread was found regular, not interrupted and ascending along the superior hemorrhoidal artery. 1212 glands were studied from the abdomino-perineal resected specimens.

Larson in an excellent paper reviews the necropsy findings in 210 cases of malignant lesions of the colon both non-surgical as well as 86 surgical. 37% (77) showed no metastases and 113 showed none or only a few glands in the immediate resectible zone. The study shows the older the patient the less likelihood of metastases. The greatest frequency of occurrence was in the two extremes of the bowel, and more than half of the growths could have been visualized by proctoscopic or sigmoidoscopic examination since they were in the sigmoid, recto-sigmoid, and rectum.

DIAGNOSIS AND SYMPTOMATOLOGY

Steindl stresses the diagnosis and recognition of early symptoms of cancer of the rectum. He states Germany and America lead in providing organized clinics for regular prophylactic examinations. Systematic rectal examination in all even slightly suspicious cases should be included in an obligatory plan. He states the need for a low priced proctoscope, the advance in roentgenography oral and enema relief pictures, and air inflation to demonstrate functional and morphologic changes. The earliest symptoms are irregularity of bowel action, and the passage of blood and mucus. Later symptoms, pain, tenesmus, foreign body in rectum occur in varying degrees and combination and are not a dependable symptom-complex.

Shaw emphasizes the early symptoms of cancer of the large bowel. He states that the symptoms and signs of the right half of the large intestine are suggestive but not diagnostic. They may be dull inconstant pain, vague indigestion, anemia, weakness, change in intestinal habit, occult blood, and possibly a tumor mass. Loss of weight and cachexia are late manifestations. On the left side the symptoms are symptoms of complete or partial obstruction, change in intestinal habit, rumbling or visible peristalsis, and a tumor mass revealed by rectal examination.

E. A. Daniels stresses early diagnosis and in a pathological and clinical study of 215 cases found cases divided into 3 classes — mucosal involvement 18%, perirectal tissues invasion but no glandular involvement 35%, and where regional lymphatics were involved 47%. In three years of the three classes alive and well in 60 follow-ups there were respectively 86%, 73% and 19%.

F. J. Smith states many cases of carcinoma of the sigmoid show only gradual increasing constipation until suddenly obstructed.

Moir among cases cited mentions sudden perforation of the sigmoid near its mesenteric border from an obstructive cancer lesion with no preceding symptoms.

Dixon and *Stevens* state in rectal cancer bleeding is the most prominent symptom in 85% of cases and may be the only sign, whereas anemia may be the only outstanding symptom in right colonic lesions.

Raiford reviews and studies 511 cases of carcinoma of the colon and rectum at the Johns Hopkins Hospital from 1900 to 1930. 192 were colon and 319 rectal. The sigmoid and descending colon were most frequently involved in the colon series and the cecum and ascending colon nearly in equal numbers. Medullary and primary mucoid showed the poorest prognosis, and adenocarcinoma with mucoid degenerations, grade one adenocarcinoma, and scirrhous carcinoma gave the best prognosis. Indefinite premonitory symptoms of epigastric discomfort, occasional regurgitation, moderate distention, and change in bowel function are present in the early or slow growing cancer.

OPERATIONS

FIRST STAGE—SECOND STAGE—PERINEAL

In general, opinion favors the two stage operation, and the abdomino-perineal operation is the operation of choice. One stage advocates of the latter advise it for the most part only when the bowel is empty and when the general condition, age and such factors permit it. The perineal resection remains in favor in selected cases and even yet has its advocates to the exclusion of the abdominoperineal.

Morand advocates the perineal or sacral amputation, shows a 50% five year cure and stresses that the operative risk is minimal.

Dixon advocates perineal resection in all cases over 55 years of age, and abdominoperineal only where the general condition and age permit it. He agrees with Lockhart-Mummery that recurrences are most likely in that group where lymphatic node involvement as well as intestinal wall extension are present.

Raiford, judging from his review of cases at the Johns Hopkins Hospital, states that combined abdomino-perineal resection is the method of choice rather than the perineal or sacral, although the operative mortality was much higher in the one stage. 5 year arrests rose from 25% in 1900-1905 to 36% in 1920-1925. In 192 colon cases during the same periods the 5 year arrests or cures rose from 14.6% to 28% and a decrease in postoperative mortality from 31% to 17.3%, whereas the operability increased from 24.1% to 65.5%.

In Germany, *Devist, Madlener, Lexer* and *Naegeli* according to *Taumann* favor the two stage resection, while *Van Haberer* performs a one stage of the colon with a Witzel ileostomy even in cases with ileus.

Finsterer states he differs from Moskowicz who favors a two stage operation of the colon and believes a one stage operation is justified when the intestine is empty, since the mortality is only 12.5% if the operation is carried out under local anesthesia and the sectioned intestine is anastomosed side-to-side. The author reports 132 cases. It is not done as a one stage when acute obstruction is present, but as a three stage resection with side to side anastomosis 1 week after the construction of a fecal fistula. One death occurred in 17 such cases. If the intestine cannot be emptied but there is no acute ileus, choice must be made between a two and three stage operation. In 22 three stage operations, 4 terminated fatally. In the one stage operation on the right and the left side the mortality was 21%.

Partsch states the mortality in one stage and multiple stages in colon cancer is equal, and therefore favors the former.

Yeomans states the one stage abdominoperineal operation of Miles is applicable in 60% of all rectosigmoid cancers and is ideal from the standpoint of wide eradication of the disease and the prevention of recurrences. States the two stage procedure has distinct advantage over the one stage in greater safety and applicability to cases where one stage would be too great a hazard. A rehabilitation of the patient between stages occurs and the lower loop irrigation reduces the inflammation of the injected cancer segment. In selected cases Yoemans advocates perineal resection with anal restoration.

Krause in obstructed right sided colon cases favors a two or three stage operation, otherwise a one stage, and performs an end to side ileocolostomy.

N. B. Anderson favors a two stage Lahey method.

T. E. Jones favors the one stage abdomino-perineal operation and cites 135 cases with a mortality of 11% which he believes compares favorably with the two stage if the mortality of the two operations were to be included. The percentage of immunity from carcinoma over 5 years is 52%, over 3 years 62% and 67% for any time less.

Rankin advocates the two stage Miles operation inasmuch as the one stage offers too formidable a risk to most patients. Mummery operation with colostomy and posterior resection he believes too limited a glandular removal. The Jones operation is a satisfactory procedure but the loop colostomy sometimes leaves a mucus fistula posteriorly. Of 300 cases colon and rectal cancer previously reported 13% were grade I, 58% grade II, 21% grade III, and 8% grade IV. The operative mortality stays at 10%, and one or two stage abdominoperineal resections of 99 cases the last 4 years has been 8% with operability at 60%. Whereas the operative mortality is 5% in posterior resection the 5 year results in 300 cases show only a 38% 5 year cure as compared to the one stage Miles 3 year cure of 79%.

Several new points of surgical technic have been published.

Trueblood submits an abdominoperineal operation that requires two operating groups—one for the abdomen and one group for the anus and perineum. The patient is placed in the lithotomy position with the table tilted in Trendelenburg. Each group facilitates the other.

MacGuire performs a preliminary cecostomy and may even delay operation for 2 months if necessary to prepare the patient generally. The operation is performed then as a one stage abdominoperineal resection. After dissecting to below the peritoneal reflection the abdomen is temporarily closed and the perineal resection done in the lithotomy position, the lower segment covered with a rubber glove, the abdomen reopened and the resection completed.

Devine basing his operation on experimental work in animals where isolated colon loops are found bacteria-free, does a transverse colon division and bring the ends to the abdominal wound margin. Resection follows some weeks later. Six months later the rectal stump in the rectosigmoid resection is united to a mobilized sigmoid by telescoping the latter into it. The colonic segments are reunited and the artificial anus is closed in the usual Mikulicz fashion.

MIKULICZ PROCEDURE

The Mikulicz procedure and its modifications and mobilization and transposition operations of the colon received considerable attention.

Moskowicz advocates a return to the Mikulicz 4 stage resection which should include the mesocolon and its glands, should include a suturing of the efferent and afferent loops uniting them on the mesenteric site for a distance of 10 cm. or the distance to which the enterotome is to be applied. The closure may be improved by cauterizing the mucosal aspect to retract the stoma inward and close it extraperitoneally. The procedure reduced von Mikulicz' mortality from 50% to 12.5% whereas the one stage resection advocated by Nordmann carries a mortality of 33%, in the large clinics notwithstanding. Advocates loop limb suture and the pacquelin cautery to the colostomy stoma to narrow the size.

OTHER CONSERVATIVE AND EXTERIORIZATION METHODS

There is quite a marked tendency towards more conservative measures in operative procedure on the colon and rectum. Apart from the Mikulicz procedures which is again brought to the fore are operations devised to gain asepsis through exteriorization methods.

An outstanding paper is that of *Koster* who advocates resection of either the right or left colon by means of a loin incision and a retroperitoneal approach. Abdominal exploration and anastomosis of the bowel is done as a preliminary procedure. Advantages gained are through wide exposure and lymphatic excision and extraperitoneal plantation of the divided limbs of the colon.

Collins combines an obstructive resection with a Mikulicz clamping of an intended spur of the remaining limbs of a resected right colon, but adaptible to other portions of the colon. The usual intra-abdominal peritoneallization and drainage is done. Preliminary cecostomy decompression is avoided.

Goldschmidt quotes 7 cases of chronic inflammatory tumors responding to laparotomy and drainage.

Dixon describes two cases of previously resected sigmoids where mobilization by separation of the outer leaf of descending colon peritoneal reflection permitted bowel restoration.

Preliminary decompression to surgical resections of the colon is urged by *Krause* who advocates Witzel ileostomy, *MacQuire* who describes an original permanent ileostomy, and *Glenn* who advocates transverse colon colostomy.

COLOSTOMY

Best and *Hicken* describe a plastic operation for the cicatrized and retracted colostomy which prevents stenosis recurring by mucosal suturing and elevation of the colostomy and suturing to a surrounding rubber doughnut.

Landsman describes the post-operative care of the colostomy and advocates the use of a rubber spool as an aid to fecal control.

Warwick discusses the colostomy faults and complications and describes a colostomy wherein fascial suturing by external oblique or thigh transplant through a holed incision is done.

Dixon advocates colostomy in debilitated patients for cancer of the upper sigmoid followed by later abdominoperineal resection.

Nobuoka describes 3 cases where he adapts the Kurtzahn's method for constructing a closable anus.

THE CONSERVATIVE OPERATION

The conservative operation for sphincter control has aroused considerable discussion and has its staunch advocates.

Breitkapf reports a consecutive series of 19 cases where sphincter preservation following rectal resection was obtained. Besides the pull through method of Hochenegg and the circular suture according to the Küttner method, the operation used was with anal mucosa resection both with or without sphincter division.

Turner reported 19 such cases before the British Royal Society of Medicine. Colostomy preceded only 6 of the 19. The operation is suitable in only 5% of all cases coming to surgery. There was but one death. Gabriel in discussing his paper states only 11% or 16 cases of those operated upon at St. Mark's Hospital. He did not favor it. Neither did Lockhart-Mummery. Sir Gordon Watson favored it where large papillomata are involved. Rayner described a modified Hochenegg procedure.

Mandl describes and advocates his modified Hochenegg procedure and states that though this "extended sacral operation" is not suitable for all operations, other operative measures may be permissable such as endorectal electrocoagulation and linear rectotomy.

Steindl agrees with Mandl that such an operation is advisable in certain cases and believes the radical removal of pararectal tissue is the point par excellence.

Gold and *Stritko* advise the Mandl operation but state high lying tumors require abdomino-perineal resections and that a narrow pelvis and such causes are contra-indications for the Mandl operation. State the abdominoperineal operation has come into disrepute because of its high mortality.

CARCINOMATOUS INVASION OF THE COLON

A very unusual case is reported by *Lawrence* and *Steele* where an infiltrating carcinomatous ulcer of the stomach located 2 inches from the pylorus was found to have secondarily invaded the rectum, the cecum and ascending colon, and the splenic flexure. All had diffuse thickening of the wall and associated constriction of the lumen.

Duval describes his technic for gastrectomy and colectomy for neoplasm of the stomach with adherence to the transverse colon.

Reducing FECAL TOXICITY

● Whenever the bowel loses its normal selectivity and the liver's ability to detoxify is overtaxed, a flood of toxic material enters the system.

Soricin detoxifies at the port of entry—the bowel.

Soricin is not a panacea—it is merely an effective means of decreasing toxic absorption from the enteric tract.

Soricin inhibits putrefaction and abnormal bacterial proteolysis.

Soricin detoxifies many toxic substances present in the bowel contents. The continued use of Soricin aids in desensitizing the patient who has become sensitized to his intestinal flora and their autolysates.

Specifically, Soricin is useful in the treatment and prevention of: Bacterial hypersensitivity of the intestinal tract, Intestinal allergy, Intestinal toxemia, Allergic diarrhea, Urticaria, Angioneurotic edema.

Consequently, Soricin is of value in the treatment of many conditions such as headache, vertigo, anorexia, migraine, and urticaria when of intestinal origin. Likewise, cases of mucous colitis, ulcerative colitis and similar local affections have been greatly improved by the use of Soricin Capsules or Soricin Tablets.

Soricin-Merrell

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes. Soricin Tablets—Enteric coated tablets each containing five grains of sodium ricinoleate.

COLON

CHRONIC ULCERATIVE COLITIS

(Idiopathic Ulcerative Colitis—Non-Specific Ulcerative Colitis — Bacillary Dysentery).

BARGEN'S DIPLOSTREPTOCOCCUS

Bargen has published a book on "The Management of Colitis" in which in addition to covering the various colitides in detail especial emphasis is given to chronic ulcerative colitis.

Bargen and *Kemble* review in careful detail the predisposing factors in 20 cases of chronic ulcerative colitis.

Brust and *Bargen* reviewing 1291 cases seen at the Mayo Clinic between 1924 and 1932 found only 25 or 1.9% over 60 years of age. Of these 25, 16 were males and 9 females. None had polyps, one had carcinoma of the bowel. All but 2 cases responded very well to vaccine therapy. 20 were greatly improved in 2 weeks.

Bargen and *Dixon* review 25 cases of carcinoma and 2 cases of lymphosarcoma of the colon associated with chronic ulcerative colitis. Conclusions drawn are that in the younger individual the condition likely will be fulminating and multiple and that vaccine therapy is decidedly indicated.

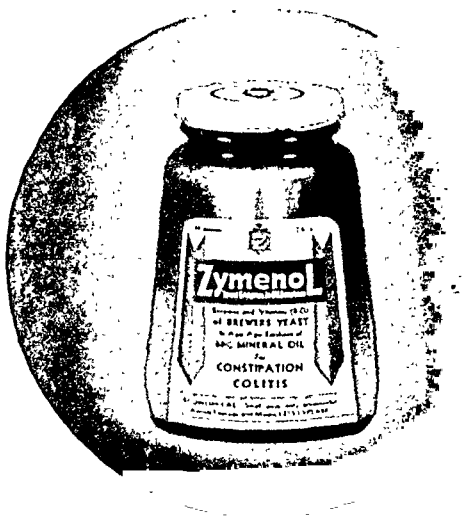
Gallart Mones and *Domingo* from a bacteriologic study of 25 cases conclude that although the Bargen and Buttinux organisms are frequently found they resemble streptococcus mitis on the one hand and streptococcus saprophyticus on the other and are not in their opinion specific. In the rabbit ordinarily non-virulent organism are virulent when obtained from ulcerative colitis patients.

Hare in his presidential address before the Royal Society of Medicine discusses ulcerative colitis. States that Hern found 50% of his cases benefited through the use of Bargen's vaccine. Although Hurst reports good results with antidysenteric serum the author could not substantiate the same in his own cases. Clinically no substantiation could be given by the author to the experimental work by Cramer with Vitamin A and McCarrion with vitamin B. The author reports a macrocytic type of anemia in an ulcerative colitis case that responded to liver therapy.

Howe reviews 20 cases seen in 6 years treated with autogenous vaccine, brewers yeast, haliver oil or vitamins and the usual dietary management. 30% are well, 35% markedly improved, 15% moderately improved, and 20% died.

Radner cites 16 cases and treated 8 cases with the autogenous Bargen diplostreptococcus vaccine, with remarkably good results in 5 cases. 2 additional cases showed an associated endomoeba histolytic, and 2 the streptococcus hemolyticus.

B. DYSENTERIAE



Crohn and *Rosenak* in a review of 90 cases where mainly through the use of polyvalent anti-dysenteric serum given intravenously, and associated treatment such as acriflavin retention enemas, diet and the usual medicinal measures state 44.5% were cured, 30% improved and only 10% not improved. The authors are enthusiastic over Bargen's fine therapeutic results but do not accept the diplostreptococcus as being the proven cause of this disease.

Felsen reports an acute form of bacillary dysentery in 3 cases characterized by rapid course progressive leucopenia with granulocytopenia and fatal termination. He believes an enteric and neurotropic toxin is present, a virus causing the latter and urges early diagnosis and immediate dysenteric antitoxin. Two of the cases showed ulcerative enterocolitis and polyposis of the distal ileum and entire colon. Felsen regards chronic ulcerative colitis and regional ileitis as varied forms of bacillary dysentery.

Hurst has advocated the use of polyvalent antidysenteric serum since 1920 which he advocates at an early stage to prevent chronicity and gives in daily doses intravenously. He believes

WITHIN 10 DAYS

Even the most obstinate Constipation responds to ZYMENOL

- Only Teaspoon Dosage Required
- Does Not Contain Any Irritant Drug
- No Phenolphthalein —No Cascara —No Purgative
- A stable palatable emulsion of the enzymes and Vitamins B-G of Brewers Yeast in 60% Pure Mineral Oil.

Case reports prove the high efficacy of ZYMENOL Therapy.

The Catalytic activity provided by ZymenoL Brewers Yeast Enzymes creates and maintains a near fermentative field and favorable environment for beneficial intestinal bacteria.

Bowel contents become soft and bulky. Natural peristalsis is restored through natural impulse. Evacuation occurs daily with soft, well formed stool, without gripe, purge or irritation.

chronic ulcerative colitis due to the dysentery bacillus or an allied parenteric organism.

Winkelstein advises antidysenteric serum and bacteriophage in nonspecific ulcerative colitis obtaining positive agglutinins in 22% of such cases, and a bacteriophage potent against one or two of the strains of the b. dysenteriae in 36% of cases.

OTHER ORGANISMS

Arrese and his co-authors observing their cases for 3 years state good results followed the use of various vaccines in 22 cases. The diplostreplococcus of Bargen appeared to be identical with the enterococcus type B of Gundel and they do not believe it specific. The organism from 29 cases of ulcerative colitis cases were studied. Anaerobes particularly in Cl. perfringens variety were always found in intestinal ulcers.

Dack, Heinz and *Dragstedt* were able to produce complement fixation tests in 4 patients with chronic ulcerative colitis with antigen prepared from isolated loops of patients and from 3 experimental monkeys, using anaerobic flora which was non-spore forming and gram-negative. Similar strains were recovered from two monkeys recently recovering from the Flexner type of dysentery. The flora closely resembled bacteroides fragilis and fundiliformis actinomyces necrophorus, and the bacillus necrophorus.

MIXED VACCINE

Gesterlin and his co-authors cite good results in treatment in 15 cases where a staphylococcus, streptococcus and b. coli antivirus was used daily.

Reye reports excellent results in 6 cases using b. coli cultures from normal individuals as a retention enema, the same mixed in glucose solution.

DEFICIENCY STATES

Mackie and *Henriques* found deficiency states present in 47 of 75 cases as seen in oral mucosal changes, anemia, blood chemistry changes, and peripheral neuritis. Mackie and Pound found on further roentgenographic study disturbances of motility and such which the deficiency states could have caused by affecting the small bowel.

CALCIUM THERAPY

Haskell and *Cantarow* report on further good results by calcium and parathyreoid treatment.

Klinefelter advocates calcium therapy with high vitamin diet.

HEMOSTATIC TREATMENT

Hetenyi treats with ascorbic acid basing the effect as due to the hemostatic effect with the accompanying vitamin C deficiency on the part of the patient.

Kochs and others state pectin treatment has given good results by reason of its hemostatic effect.

Announcing:
Gerber's
Apricot and Apple Sauce . . .

a fruit combination of special importance to the Pediatrician and Dietitian.

This new addition to the Gerber family provides certain advantages hitherto unobtainable. Full ripe (not dried) apricots from the Santa Clara Valley of California are blended with select Michigan-grown apples to create a well-strained, digestible, *nutritious* combination with an important flavor factor.

Laboratory analyses of samples taken from the current pack, indicate retention to a high degree of the vitamins and minerals afforded by the original fruit, making this combination an excellent source of Vitamin A, a good source of Vitamins B, C and G, in addition to supplying some calcium, phosphorus and iron. Gerber scientific method of straining and cooking in absence of air, with evaporation of excess moisture, are employed to make possible this conservation of beneficial properties.

Pediatricians who wish to start their infant patients on a fruit diet will find this new Gerber Strained Food particularly advantageous. Dietitians will find the palatability of this combination an aid to the success of certain special diets for adults.

In Diseases of the Liver and Gall Bladder

VICHY Celestins is invariably prescribed in the important dietetic management of diseases of the liver and gall bladder, in the acute stages as well as when convalescence sets in. For such cases, in particular, its benefits have long been recognized by physicians the world over.

A valuable FREE booklet on the Therapeutic Value of Vichy with medical bibliography will be sent to any physician on request.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

THE IRRITABLE DYSFUNCTIONING COLON, CHRONIC COLITIS, OR UNSTABLE COLON

Numerous papers touch upon this subject but do not confine their subject matter to it, generalizing upon tumor growths or discussing this disease in the differential diagnostic consideration of other colopathies. Valuable and interesting contributions however have been made on the subject which include consideration from the biochemical, vitamin deficiency, allergic, psychic, emotional motor and secretory dysfunction, vagotomic, reflex, toxic and radiologic aspects.

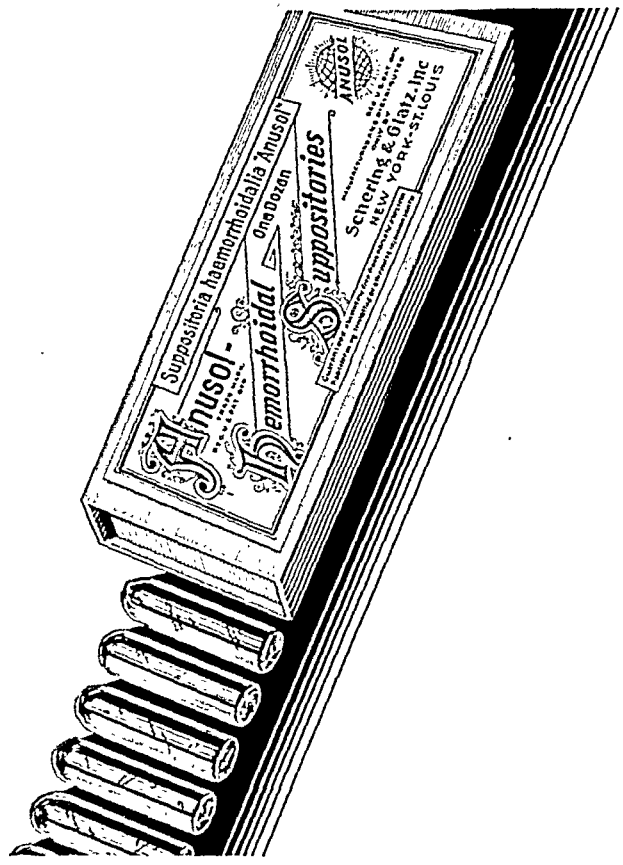
GENERAL

Gallart-Mones states that only a few of the colitides should be termed colitis. In reviewing 40 cases the dysfunction present was general, not connected with secretory insufficiency, metabolic disturbance, or hereditary factors, was suggestive of hypersensitivity, showed colonic hyperkinesis, and required individualized treatment. States these cases are pseudo-colitis.

Hurst speaks of the unhappy colon, describes the normal and pleas for sane gastro-intestinal hygiene, freedom from bowel irritants and shows how many concepts are based on erroneous anatomic and physiologic teachings.

Laus in an extremely informative paper reviews the essential colonic physiology, details the normal and abnormal stimuli and gives a comparative clinical interpretation based on numerous case studies.

ALLERGY



Alvarez states that digestibility of foodstuffs varies with individual susceptibility and that food sensitivity should not be laid totally to allergic sensitivity.

Wiltsie states that he disagrees with Alvarez and states that all symptoms of which a patient might complain seem to be due directly or indirectly to intestinal toxemia. Advocates mainly colonic irrigation.

Hare states that 85% of 38 patients had a personal or family history of allergy and considers that factor as important and is in accordance with Pearson's findings in 1933 where 26% of generally healthy adults show the same. Moore stresses the same.

BIOCHEMICAL

Trumper as a biochemist writes a very interesting paper and discusses the need for restoring acid-base equalibrium in the dysfunctioning colon to replace the lost minerals and to restore the proper alkali deficiency. States that colitis manifested by diarrhea not only rids the bowel of irritating substances, but also depletes it of necessary minerals, inorganic constituents and enzymes thus producing putrefaction, irritation both physical and

FOUR POINTS in the medical treatment of hemorrhoids are of utmost importance: the rectal suppository must be therapeutically effective, safe to use under any circumstances; it must be devoid of accessory or systemic effects: it must be easy and convenient to use. How well Anusol Suppositories measure up to these requirements you have probably found out by first hand experience. Shall we send you a liberal trial supply of Anusol Suppositories. Please ask for it on your letterhead.

ANUSOL SUPPOSITORIES ARE SUPPLIED IN BOXES OF 6 AND 12

ANUSOL

SCHERING & GLATZ, INC., 113 WEST 18th STREET, NEW YORK CITY

chemical, nervous instability, primary and sometimes secondary dehydration, and severe acidosis.

NEUROGENIC

Bodman cites 7 cases and believes that in most ulcerative colitis is a terminal stage of colon dysfunction of psychogenic origin.

Davis, Sullivan and *Young* plea for the recognition of neurogenic and psychic factors in colitis.

Morgan stresses the viscero-motor and viscero-sensory symptoms as frequently manifestations of a general body state. Classifies colitis as mucus, granulosa, atrophicans, hemorrhagica and ulcerative colitis.

REFLEX GASTRO-INTESTINAL

Bergeret and *Caroli* review 100 cases where chronic appendicitis caused colitis as was determined by appendectomy.

Feldman stresses the associated hyperirritability and hypermotility of the right colon with appendiceal abscess.

Mocnch in an excellent paper cites the various gynecological conditions that may give rise to gastro-intestinal symptoms and ascribes this to factors such as anatomical interrelation of blood supply, general and autonomic nervous innervation, as well as related factors of a mechanical, chemical and toxic nature.

DIETARY

Fitts describes a syndrome seen in 85 cases with B. avitaminosis with gastric atony, spastic colon, low hydrochloric acid, and mild hypothyreoidism responding to dietary measure with wheat germ.

MELANOSIS

Zobel and *Susnow* found an incidence of melanosis of 3.5% in 200 cases examined. Constipation was present and cascara sagrade was habitual.

METADYSENTERY

Castellani reports a form of colitis due to b. ceylonensis A. and B. (Castellani 1907) and b. madampensis somewhat similar to the dysentery bacillus termed metadysentery. It is characterized by recurrent dysentery with long periods of remission. Geographically it is tropical to temperate in distribution.

VACCINE

Mateer and *Baltz* in a brilliant paper discuss the results obtained in the treatment of non-ulcerative colitis or the unstable colon. 1000 cases treated during the last 4 years. 3000 cases showed skin sensitivity. The therapy was found to be a distinct value in obstinate cases as well as a valuable adjunct in the usual run of cases with chronic functional diarrhea, chronic "toxic vertigo" and chronic headaches.

Tripodi cites the results of intravenous antigonorrheal vaccine treatment in 60 duodenal ulcers and 40 chronic colitis cases with benefits marked in the former but uncertain in the latter and due to the relaxation of the smooth musculature of the bowel.

DIARRHEAS IN INFANCY AND CHILDHOOD

Terrell and *Owen* report an epidemic occurring near Fort Worth, Texas, effecting thousands of adults but predominantly infants and children. All cases showed a predominating large gram-positive diplostreptococcus. 14 cases were negative to agglutination for the various dysenteries and typhoid. Autopsies revealed a hemorrhagic mucosa and lymphoid hyperplasia with superficial ulceration with cultures showing the same organism. Rabbit inoculation caused mucosal congestion, large amounts of mucus and bloody mucus but no ulcerations.

Johnston and *Kaake* describe an epidemic in the nursery of a small Toronto Hospital where in 15 cases involved, 9 deaths occurred, due apparently to b. dispar. Reports two previous epidemics one of 1931 and one of September, 1934, due apparently to b. dysenteriae (Sonne).

Loeschke shows that in severe toxic dysenteries in childhood severe toxicity

Recommended Medium for

Barium Sulphate Suspension

Here is how Horlick's Malted Milk meets the requirements for the contrast meal in gastro-intestinal diagnosis by X-Ray:

1. PALATABILITY

Horlick's effectively disguises taste of the barium sulphate. Affords definite amount of easily digested, suitably balanced food material.

2. UNIFORM SUSPENSION

Horlick's colloidal constituents, notably the dextrins and gluten derived from malted cereals, and the albumin of the milk, make for uniform dispersion—a stable suspension, and shadow of even density.

3. EXPULSION TIME

Well within normal limits.

4. PENETRATION

The barium meal prepared with Horlick's penetrates the gastro-intestinal tract throughout. Unlike meals which must be given cold to disguise degree of acidity, Horlick's may be given at body temperatures. Thus it will not disturb correct stomach motility, make diagnosis less certain.

5. NEUTRALITY

Does not over-stimulate or neutralize gastric secretions, for the partial predigestion of the food elements and the formation of an exceedingly fine curd give Horlick's a neutral quality in the alimentary tract.

6. NON-CONSTIPATING

Horlick's does not lump or constipate.

7. NON-IRRITATING

Neither burdensome nor irritating to diseased mucous membrane. Does not interfere with regular action of pylorus.

8. DEFINITE COMPOSITION

By observing proportion of Horlick formulas, technician can be sure of solution uniform in character. Horlick's gives smooth, homogeneous suspension. Radiographs will be singularly free from defects attributable to character of suspension medium.

9. CONVENIENT

Horlick's is easily and quickly prepared as needed. No waste. Either the natural or chocolate flavor of Horlick's may be used, according to patient's taste.

HORLICK'S
The Original Malted Milk is without an equal

Experience has shown — in many physicians' and hospital laboratories, Horlick's has been in continuous use for decades. Dependable, not loaded with a cloying sugar, raw cocoa or synthetic flavors.

HORLICK'S MALTED MILK

GRANULES
STEARNS

Mucilose

To increase the convenience of Mucilose administration and at the same time preserve its valuable corrective efficiency in constipation and spastic colitis, Mucilose has been made available in a new, palatable, granular form.

VERY EASY TO TAKE—It is easy to take Mucilose Granules even in the dry state. Just place the dose on the tongue and wash down with water. Of course, if preferred, the patient may take it in milk or fruit juices.

Whatever method is used, liberal quantities of water are essential.

Mucilose is a specially prepared hemicellulose obtained from the Plantago Loeflingii. Extensive clinical investigation has shown it to be definitely corrective in constipation and spastic colitis.

Mucilose produces bland, non-irritating distention in the bowel, lubricates without leakage, produces large, formed, soft stools.

DOLICHOCOLON

ETIOLOGY AND PATHOLOGY

Bernard believes that dolichocolon is postembryonic due to an anatomical-clinical entity leading to a disturbance of motility by reason of an anomaly of fixation or length of mesentery.

Blanco reviews the theories of origin and classifies according to sigmoid, descending or transverse, demonstrating cases in children with radiograms.

TREATMENT

Seneque and *Milhiet* describe a one stage exteriorized anastomosis.

Nard describes a technique which by a lateral Trendelenburg position and a transverse incision permits better exposure.

Rapid Control of Pain

with

Creamalin

The Specially Prepared Colloidal Cream of Aluminum Hydroxide for

PEPTIC ULCER

"Pain disappeared after the first dose" is the significant comment of many clinicians in reporting their experiences with Creamalin therapy.

The ability of Creamalin to control pain and pylorospasm speedily is undoubtedly due to its unique astringent properties as well as to its rapid acid-fixing action. The special process employed in the preparation of Creamalin may well account for its unusual analgesic action. Try Creamalin and observe its rapid effect on pain.

The Creamalin Continuous Drip Treatment. Although Creamalin has yielded gratifying results in thousands of cases of peptic ulcer when administered orally, certain types of cases are more amenable to a form of treatment whereby diluted Creamalin is administered as a continuous drip. These cases include those 1) wherever a high nocturnal acidity renders the case refractory to intermittent oral treatment; 2) bleeding ulcers; 3) the generally refractory type. In one institution alone, 142 cases have been treated by the Creamalin Drip, and with one exception, x-ray findings were negative in from seven to ten days.

The Creamalin Automatic Drip Control, designed to simplify and facilitate the technique of continuous drip administration, now makes the whole therapy a simple routine. Write for information and for material for clinical evaluation.

CLEVELAND CHEMICAL ASSOCIATES

3616 Euclid Avenue

Cleveland, Ohio

ileitis or chronic cicatrizing enteritis is reported by *Erb* who reports 4 cases with pathology limited to this region characterized by edema, congestion, lymphoid tissue inflammation, necrosis and symptoms of severe prostration and characteristic of appendicitis. He states that these cases were similar if not actually the same as those described by Crohn et al, Harris, Bell and Brunn.

A similar case is reported at the Cabot Clinic.

Felsen reports a summary of evidence which he has accumulated in support of his contention that bacillary dysentery, distal ileitis, and non-specific ulcerative colitis are different stages or manifestations of the same disease.

INFLAMMATORY LESIONS

Brücke reports a case of ischemic stenosis of the transverse colon 11 days after ligation of the middle colic artery.

Hardt reports an unusual case of emphysema of the cecum. No cause was found and the cultures from the air blebs were negative.

Bargen, J. A. and Dixon, C. F.: Regional Ileitis. *Proceedings of the Staff Meetings of the Mayo Clinic*, 10:814, Dec., 18, 1935.

Hardt, L. L.: Emphysema of the Cecum. *J. A. M. A.*, 105:1982, Dec. 14, 1935.

MECHANICAL AND TRAUMATIC CONDITIONS OF THE COLON

Cunniffé reports an intussusception of a cancer of the descending colon treated successfully by Mikulicz operation and diagnosed pre-operatively by X-ray.

Hardouin reports 4 cases of volvulus of the sigmoid and advises immediate resection if possible in all such cases.

McClure reports a case of torsion of the entire small bowel with symptoms of persistent constipation, umbilical pain, meteorism, vomiting, etc.

Saeltzer and *Rhodes* report 5 cases where terminal colon lesions resulted in diastasic perforation of the cecum.

Vanlande reports volvulus of the pelvic colon in 2 cases.

Walkling reports a ruptured sigmoid in a 60 year old male due to inserting a brass nozzle sprinkler into the rectum in the attempt to give an enema.

(See also congenital anomalies and dolichocolon).

MEGACOLON

ETIOLOGY AND PATHOLOGY

Freeman states that whereas some maintain rectosigmoidal spasm is responsible for megacolon, the trouble is mainly due to sympathetic and parasympathetic unbalance inasmuch as lumbar ganglionectomy improves the condition. Believes sphincter spasm may lead to megacolon and frequently accompanies the pathology.

Zander describes a case necessitating right colon resection that came by reason of previous surgery for constipation where an exclusion of the colon had been done.

Pitman describes a case where dilatation and stasis of the proximal colon came secondarily to a napkin ring defect just above the cecum as well as because of the added pathology of herniation of the stomach.

Caciro describes a valvular megasigmoid originally described by Riedel and Perthes which showed a fecalith of enormous size at 16-17 cm. distance from the anus in the megasigmoid where a true spur was found and behind it the base of the cavity.

TREATMENT

Hueck believes in surgical resections in certain selected cases.

Orator states the need for individualization in treatment and cites three cases to demonstrate his point. One case he states showed a congenital maldevelopment of the sacral parasympathetic nervous system and would respond to lumbar sympathectomy, but another case cited seemed to indicate a pathological overstimulation of the parasympathic nerves and by this procedure would be made only worse.

Rankin reports 10 cases operated upon. Favors inferior mesenteric presacral nerve section. 7 cases were for congenital idiopathic Hirschsprung's Disease and 3 for constipation. Believes that the aorticorenal or renal periarterial plexus is joined by the branches of the first and second lumbar ganglions to form the intermesenteric plexus so that lumbar ramisectomy and ganglionectomy may affect the descending colon, sigmoid, rectum and internal sphincter by reason of the innervation to colon and rectum.

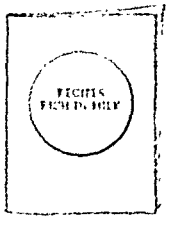
Dominici favors expectant treatment and surgical treatment only if this fails.

Rives and *Strug* report that a case reported previously with S. J. Stabins where spinal anesthesia was used therapeutically has remained well for 4 years. Refer also to good results obtained in another patient with megacolon and two patients with obstinate constipation so treated and reported by these co-authors in January, 1935. The

PROTECTION

plus Protection

The manner and the extent to which milk is capable of correcting dietary deficiencies has caused it to be called "a protective food."



Providing that "protection" in full measure, Pet Milk furnishes an additional protection—complete and sure protection against milk-borne infection.

Sterilized in sealed containers, Irradiated Pet Milk can never introduce bacteria to cause disease or digestive disturbance.

Uniformly rich in all of the food substances which milk can be relied upon to furnish, plus an extra amount of vitamin D created by irradiation, Pet Milk is also more readily digestible than ordinary milk, less likely to cause allergic disturbance, and lower in cost.

For "protection" plus, prescribe Irradiated Pet Milk.

Samples and literature will be sent on request.

PET MILK COMPANY, 1446c Arcade Building, St. Louis, Mo.

TRI-CALSATE

A Powerful Neutralizer

Neutralizes HCL, yet does not alkalizes the stomach contents

TRI-CALSATE is a buffered neutral antacid that eliminates the disadvantages of the alkaline antacids. For the distressing symptoms of peptic ulcer, heartburn, hyperchlorhydria, etc., Tri-Calsate provides rapid relief without harmful systemic effects.

Tri-Calsate is non-toxic, non-irritating, palatable and ECONOMICAL. The quantity in the large size bottle has been increased from 16 to 18 oz. at no increase in price, making in effect a ten per cent reduction in price to the patient.

Available on prescription at your pharmacy or direct in 4-oz. and 18-oz. bottles.

AVOID

The Vicious Circle Of Alkali Neutralization.

TRI-CALSATE *is a* buffered antacid--neutralizes without alkalosis

PHYSIOLOGY OF THE COLON

Very valuable contributions were given to our specialty in this field of research.

FECES

Pachioli and *Mengoli* by a colorimetric study of the stools of 381 children states that breast fed infants stools are acid showing a p.h. of 5.6, that the p.h. value varies with the diet and that after 2 years of age the stools are alkaline and not influenced by diet.

Goiffon has published a manual describing the normal formation of feces, the examination, evaluation and the therapeutic considerations of fecal examination for clinical purpose.

Amalfitano in two separate articles describes an acetic acid test for albumen which is indicative he states of intestinal ulceration, and studied the presence of amylase in 24 cases claiming an increase in chronic inflammatory intestinal disorders and a decrease in the acute.

Boas and *Häcker* in separate articles attempt to evaluate the Boas test of feces and state the presence of unchanged hemoglobin and copratoporphyrin signifies the suspicion of cancer.

Ehlert and *Fetwurst* state a greatly reduced value of urobilinogen is highly significant of cancer present below the cardia 27 of 31 cases of carcinoma having fecal values indicating cancer.

Steggerda found in the study of feces in humans and dogs that the rectal end is 10% more concentrated than the colon end, and that the proximal colon is 10% more concentrated than the cecum, which he believes is directly related to the proportionate degree of vascularity of those portions of the bowel.

THE NERVOUS MECHANISM CONCERNED IN COLON FUNCTION

Kobat, Anson, Magoun and *Ranson* experiments are a distinct contribution. By faradic stimulation of the lateral hypothalamic area in the unanesthetized cat they produced the same sympathetic response described by Cannon in his emotionally excited cats and produced an inhibition of gastro-intestinal motility. The supramamillary commissure produced the same results suggesting this to be an afferent pathway to the gut.

M'Fadden, Loughridge and *Milroy* studied one or more of the nerve pathways to the distal colon and observed the effect upon the colon motility following severance. Interruption of sympathetic pathways leads to sphincter relaxation and an atonic dilated colon. Section of the pelvic nerves or dornal sacral roots caused a hypermotile colon and spastic sphincter.

Denny and *Graeme* described and studied the reflex act of defication finding that the sacral segments of the cord cause greater fusion of rectal contractions, whereas the sympathetic nerve supply through the hypogastric to the anus and rectum does not. The mechanism of defecation depends upon the reaction of the rectum to distention. Automatic and reflex responses come also from cutaneous area of sacral segments.

Arendt on the basis of radiologic study states the junction of the first and middle third of the transverse colon constitutes the Cannon-Böhm point which is the point of change from upper splanchnic innervation to the lower innervation of the vagus and the pelvic plexus.

Kolossow and *Polykarpowa* by sectioning the hypogastric nerves found that the sympathetic nerves of the rectum are postganglionic fibers of the same nerve elements present in extramural ganglions and that the fibers are actually axon ganglion cells.

MOTILITY CHANGES IN THE COLON

Kreuzfuchs states that the capacity of the colon is necessary information to interpretation of the mechanism of evacuation.

Sparks and *Colins* working on rats with carefully controlled diet and control series substantiate the work of Hargreaves, Fletcher and Dickson, and show that the volume of the colon if maintained on a diet deficient in vitamin B increased strikingly.

Okae found a direct relationship between peristalsis and increased circulation of blood in the bowel wall. The effect of numerous drugs were studied in this respect. Peristalsis was definitely effected by pituglandol, esserin, prostigmin and barium chloride.

C. Goldman with a study based on a

To those who have never used

KAOMAGMA*

Dear Doctor:

Test Kaomagma on your next case of diarrhea, intestinal toxemia or colitis. You will find it stops diarrhea quicker, checks dehydration more readily and is definitely soothing to inflamed intestinal mucosa.

Kaomagma does not disturb normal digestive processes nor is its use accompanied by flatulence or abdominal distress.

We suggest that you investigate Kaomagma—give it a thorough clinical trial. We are confident of its ability to more than meet your expectations.

Very truly yours,
JOHN WYETH & BROTHER, Inc.

*Kaomagma is an activated fluid dispersion of finest medicinal kaolin in colloidal aluminum hydroxide. Available in two forms: Kaomagma Plain, for use where intestinal disturbances are associated with diarrhea, and Kaomagma with Mineral Oil, for those cases in which constipation is present. Both forms are available in 12-ounce bottles.

Special Tumors of the Colon Other Than Adenomas

Bartlett reports a case of endometrial tumor of the intramuscular portion of the sigmoid bowel wall, thought by the author to be embryonal.

Böhm reports a lymphatic cystoma of the descending colon.

Geschickter reports 178 cases of benign tumors with the following incidence:

	Total	Colon	Rectum	Retroperitoneal
Adenomas	90	10	55	
Argentaffine tumors	36	2		
Enteric cyst	1			1
Myomas	24		1	
Angiomas	6		1	

Konjetzny reports 2 cases of endometriosis of the lower segment of the sigmoid, one confined to the longitudinal muscle layer and one penetrating the entire muscular layer.

Melicow cites four cases of xanthic lesions one of which was of the cecum and ascending colon due to kidney sinus. The xanthic change is due to excess of lipoids on the basis of lipogenic response by cells of the reticuloendothelial system.

Varner reports a sigmoid myoma successfully removed by two stage resection.

Bargen and *Dixon* review 2 cases of lymphosarcoma of the colon.

Bargen, J. A. and Dixon, C. F.: Chronic Ulcerative Colitis with Associated Carcinoma. Progress in Management. *Arch. Surg.*, 30:851, May, 1935.

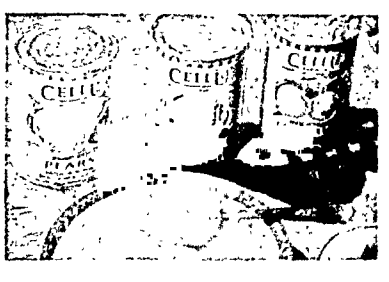
Congenital Anomalies



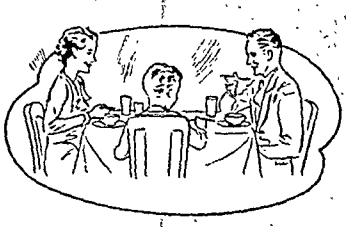
There is a considerable number of case reports covering imperforate anus, vestibular and vulvar anus and congenital anorectal atresia.

Klinefelter reports a completely absent colon in an otherwise normal newborn. *Patel* reports a case showing total atresia in a 57 year old adult with symptoms present since 15 years of age interpreted as doubtfully congenital but with congenital disposition towards atresia.

The omentocolic membrane and the ligaments of the right colonic angle are discussed in reference to intestinal obstruction.

A large number of cases are reported where with abnormal rotation cecal volvulus occurred due to mobile ileum, and cecum with inverted cecum, and other anomilies of ileocolic fixation. *Consiglio* states many asymptomatic cases of mobile cecum occur and in most cases of acute appendicitis may be a predisposing cause.

Sweet reviews acute and chronic volvulus of the cecum from the records of the Massachusetts General Hospital from 1873 to 1930. Exclusive of strangulated hernia 7 cases are re-



WITHOUT SUGAR
CELLU CANNED FRUITS

When patients must follow low carbohydrate diets, Cellu Canned Fruits are often suggested. They are packed in water, without added sugar, and, for this reason, give the variety so necessary in the diet, yet keep carbohydrate intake relatively low. The secret of Cellu flavor lies in the true sun-ripened fruit used exclusively. For the quantitative diet, food values are shown on the labels. Write for a free sample and complete list of Cellu Foods.

For the "Quickly Available Energy" Food at Breakfast

When a Bland, Non-Irritating Food is Required

For Baby's First Cereal Food

THESE *are the Important Points, Doctor...*

In your choice of the infant's first cereal food, of the "energy element" in the dietary of growing children and adults, and of a highly nutrient factor in the bland diet indicated in certain syndromes and convalescence, Cream of Wheat merits your consideration because of these features:

Nutritional Value

An ounce of Cream of Wheat yields 115 calories of valuable food energy—protein, 11.8%; fat, 2.4%; and carbohydrate, 72.5%.

Palatability

The appealing taste of Cream of Wheat is pleasing and satisfying. It may be eaten daily, for long periods, without tiring the palate, an especially important point in the dietary of children and convalescents.

Economy

The large package of Cream of Wheat makes six and one-half *quarts* of cooked cereal, fifty generous servings, at less than half a penny each. Your patients, doctor, will quickly recognize this outstanding food value.

ACCEPTED AMERICAN MEDICAL ASSN. Council on Food

CREAM of WHEAT

THE CREAM OF WHEAT CORPORATION

MINNEAPOLIS, MINN., U. S. A.

ported. 520 cases of acute volvulus were recorded. 11.3% were cecal, 18.8% sigmoid and 67.9% small bowel.

Retroposition of the transverse colon is discussed by *Truesdale* who cites the 12th reported case.

Callender and others report an anomaly where jejunal ileal herniation occurred into mesocolon.

Numerous reports of sigmoid volvulus are in foreign articles.

(Also see Dolichocolon).

Truesdale, P. E.: Retroposition of Transverse Colon; 2 Cases. *J. A. M. A.*, 104:1697, May 11, 1935.

CONSTIPATION

General

The majority of authors on this subject agree with the expression of *Douthwaite* who states "It is sad to reflect that one of the greatest advances in the treatment of gastro-intestinal diseases is being obstructed by the reluctance of the patient to accept simple remedies in the place of unnecessary drugs."

Lancaster in writing about bowel training in the child states "Our experience is that the difficulty is not in getting the mother to do enough for the child, but rather to keep her within bounds and not doing too much."

Alley emphasizes the need for correcting anorectal pathology and gives a thorough rationale for good management.

Murray writes an excellent review covering the etiology and stressing individualized treatment of each case.

Investigative

Frisch experimenting with children, artifically produced constipation in 16 cases allowing bowel movements only once in every 11 days and noticed no immediate harmful results.

Pape in an excellent article reviews the roentgenologic findings in 224 pathological cases showing diagramatically the cycle of disorders of motility as compared to the normal case. The cases are divided into the hypokinetic as opposed to the hyperkinetic, that 62 cases are diarrhetic, 128 constipated, while 34 cases are called occult—that is an abnormally rapid passage combined with normal evacuation. Slightly less than half the cases of constipation showed delayed motility in the proximal colon and an equal number showed normal transport as far as the descending colon, delay beginning with passage of the sigmoid or emptying of the rectum. Only a comparatively few were hyperkinetic type showing abnormally rapid passage throughout the colon.

Physical Therapy and Colonic Irrigations

Physical therapy is recommended in a special rectal tube by *Richter* who believes the escape of gases causes a rapid disappearance of symptoms and that diet, laxatives and massage are useless in advanced conditions where toxins from constipation have affected body organs.

Friedenwald and *Morrison* state that colonic irrigations properly used are of therapeutic value in mucus colitis and intestinal stasis.

Mulinos has written a valuable and instructive article. The various drugs are discussed in detail and their chemical action explained. Laxatives and purgatives are classified as those which depend upon bulk, lubrication or upon the retention of water; those which alter the fluids of the intestine to make them less readily absorbed; and those which stimulate the small or large intestine or both.

Kovacs writes on the physical therapy treatment of constipation in an article following that of Freidenwald and Mulinos in the same journal. These articles in conjunction with each other make the subject matter well rounded. Kovacs, however, does not favor colonic irrigations although he concedes suitable medicated irrigations in colitis may temporarily be employed. Spastic constipation differing from atonic constipation requires nervous relaxation, local sedation, and heat preferably by diathermy.

Dietary and Medicinal

Bastedo writes a valuable and important article reviewing the factors of water, foods and bulk-producing laxatives in the treatment of constipation. Foods act in four ways he states, viz: by distention, mechanical irritation, chemical irritation and by reason of their vitamin content —mainly vitamin B.

Benkert reports an unusual and somewhat humorous case of a huge fecal impaction of masses of fruit seeds, skins, and whole berries.

Bondouy recommends the use of grapes in the treatment of atonic constipation in that they are rich in cellulose, sugar and organic acids.

Brunier states that in colitis with constipation the limitation of carbohydrates and malted products, the avoidance of coarse cellulose, and that the use of enemas for diarrhea are indicated.

Henderson reviews the various purgatives in an excellent well rounded paper and condemns proprietary preparations. States that Ross and Brown reported 28 deaths

"Medical Management First"

Says Dr. Jenkinson

". . . taking a patient with symptoms attributed to gallbladder disease, followed by a negative cholecystographic response, there was usually a marked improvement of the symptoms following medical management including dehydrocholic acid." † • • • Decholin (dehydrocholic acid) increases bile secretion 100% to 200%, as well as exerting a pronounced cholagogue influence. Through these actions, it washes viscid infected bile from the biliary passages, reducing absorption of toxic materials. In 3¼ gr. doses t.i.d., it is indicated in biliary engorgement, chronic cholecystitis, cholangitis, and hepatitis of toxic origin.

"...AND ONLY LIGHT, NOURISHING FOOD"

Convalescence from influenza, pneumonia and other illnesses associated with winter is a slow process, frequently requiring as much care as the acute attack. The dietary management is particularly difficult. Appetite and digestion are handicapped, yet the demand for nourishing food is increased. A diet which has proved beneficial at this time is one which supplies maximum caloric value in a palatable and easily digested form.

A Valuable Food in Convalescent Diets

Ovaltine is a food supplement which fulfills all the requirements of such a dietary regimen. It was originated, specifically, as a convalescent food. It is a highly nourishing and well balanced food. Ovaltine itself is easily digested and rapidly utilized, but in addition it increases the digestibility of the milk in which the beverage is made. It also contributes to the digestion of starches. It is palatable and helps to restore the appetite. Furthermore, Ovaltine taken at bedtime is a valuable aid in securing sound, restful sleep.

Recommend the use of Ovaltine at meals, between meals, and at bedtime during the convalescent period. It can be prescribed with confidence. Its merit is attested by over 40 years of continuous use in 57 different countries.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster

from strychnin incorporated into proprietary purgatives.

REFLEX

Crile states that peptic ulcer, chronic indigestion, and constipation may be termed kinetic diseases and in some cases curable by adrenal denervation or unilateral division of the greater splanchnic nerve.

Trumble considers that abnormal reflex activity may be responsible for certain forms of constipation and advocates sympathectomy in desperate cases to permit the colonic musculature to be released from inhibitory reflexes.

Zuckermann describes a lateral transperitoneal technique for lumbar sympathectomy and ganglionectomy for constipation.

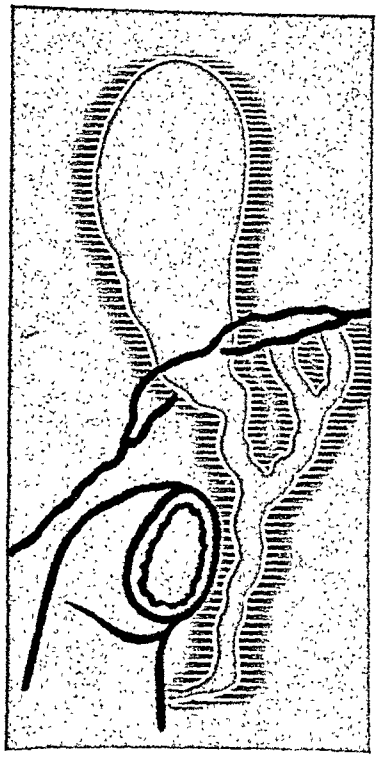
DIVERTICULOSIS AND DIVERTICULITIS

By far the most outstanding publication on this subject is that of *Lunding* who has written a monograph on the subject. The literature is a review quite complete and there is a discussion of every phase of diverticulum formation. The author bases his report on 103 cases. The cases were from 1921 to 1934. In routine colon cases X-rayed, diverticulum were present in 3.2-4.5% of cases. Males were 46.6% and females 54.4%. They were more common from 40-60 years of age. 68.9% were located in the sigmoid exclusively whereas 90.3% showed sigmoid involvement, 99% of the cases showed diverticula present either in the descending colon or sigmoid or both. 55% of cases showed inflammatory changes present as demonstrated by X-ray.



The author is of the opinion that the catalase test of fecal matter is of importance in the diagnosis and prognosis of the condition and found it increased over the normal amount in 60 pathological cases using as normal controls 93 tests from 42 normal cases. The method of Norgaard was used. The catalase is supposed to be an iron porphoryn protein compound which acts as a hydrolytic agent.

Abell studying all forms of diverticula states 5% of subjects over 40 years of age have diverticula of the colon.

Clairmont points out the dangers of diverticulosis and warns against nimless surgery.

Cone in an important paper cites a b. coli bacilluria in 3 cases of diverticulitis which he believes occurred by reason of mucosal permeability, resultant bacillemia and consequent bacilluria.

Friedenwald and *Feldman* report 50 cases ranging in

Controlling

BILIARY INFECTION

and STASIS

Chovanol meets the indications in the treatment of nonsurgical diseases of the gall-bladder and bile ducts. It reduces infection, promotes a free flow of bile and helps to prevent attacks of biliary colic.

Chovanol has given excellent results in the medical treatment of cholecystitis, cholangeitis, hepatitis and catarrhal jaundice. It is well tolerated by the stomach and is suitable for prolonged use.

DOSAGE: The customary dose for adults is 1 tablet (increased to 2 tablets if necessary), three times daily, about fifteen minutes before meals.

HOW SUPPLIED: Bottles of 50 enteric coated tablets.

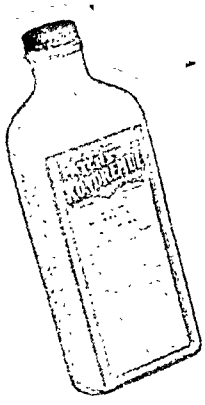
age from 34 to 79 years of age. The paper is excellently done. The authors found 8-10% of patients affected by gastro-intestinal disturbances had diverticuli, is twice as common to males as females and usually occurs after 40 years of age. Their cases also showed that it is usually multiple, occurs most frequently in the sigmoid, then in frequency of occurrence in the sigmoid, descending colon, transverse colon, ascending colon and appendix. Roentgen-ray examination showed irritable colon in 32 cases, duodenal ulcer in 2, cholecystitis in 3, adhesions in 25 and diverticula elsewhere in the gastro-intestinal tract in 4 cases. 38 cases were treated medically and 8 surgically. The authors among various methods of their outlined treatment recommend filling the diverticula with a barium bismuth mixture.

Manning reviews the subject and sanely advocates surgery for only the complicated cases and advises when surgery is resorted to, to avoid the area effected if possible.

Moynagh reports on 25 cases at St. Bartholin's Hospital in a series of papers. 16 were colon, 1 cecum, 4 duodenum, 1 stomach, 2 oesophagus, and 2 pharynx. Moynagh classifies diverticulitis as belonging to those with symptoms of obstruction, urinary symptoms or with pelvic symptoms when of the female group. They occur where conditions of stress are produced, are probably congenital and partly on a neurological basis due to a disruption of the autonomic nervous system.

Ochsner and *Bargen* state that 7% of 2,747 patients examined roentgenologically at the Mayo Clinic showed diverticulosis which being 0.4% of clinic patients is probably too low inasmuch as 6.9% were found in 447 necropsies during the same period. Males exceeded females 1.25 to 1 but diverticulitis showed 2.75 to 1. 11% showed diverticulitis and 13% gave a suggestive history of previous trouble. Constipation was present in 40% but in uncomplicated diverticulitis of the sigmoid was present in 58%. 6% of the diverticula showed malignancy.

Pessagno reports a rare case of simple diverticulitis of the cecum.



Underwood reports an analysis of 157 cases of diverticulosis as diagnosed roentgenologically at the Cleveland Clinic. 68.9% occurred in patients between 50 and 69, and sex was equally divided. 104 were sigmoid, 27 descending colon, 13 transverse colon, 6 ascending colon, 6 generallized colon, and 2 cecum. 39 cases were associated with diverticulitis or an incidence of 25%; 2 cases had an associated malignancy of the colon.

Rutledge reports a study of 70 cases of diverticulosis in which most of the cases were past 40 years of age and were victims of chronic constipation. One of the cases was a boy 17 years of age.

KONDREMUL

(CHONDRUS EMULSION)

The Finer Emulsion in Constipation

The selection of Irish Moss (Chondrus Crispus) as the emulsifying agent in Kondremul assures a tough film around each globule, so that no breaking down or separation occurs in the gastro-intestinal tract.

This means perfect mixture with the fecal mass, smooth elimination, no leakage.

The entire routine of medical treatment in constipation can be accomplished with the three types of Kondremul:

KONDREMUL with Phenolphthalein — combined laxative and regulator.

KONDREMUL with Cascara — adds the tonic laxative effect of non-bitter cascara to Kondremul.

KONDREMUL Plain — a corrective for deficient bowel action.

"... we know that in the infant and growing child alkali in excess of acid must be stored."

Growth and Development of the Child, Part III, White House Conference on Child Health and Protection, New York, 1932, p. 213.

BUT—

many diets are acid-forming

AS pointed out in the Journal of the American Medical Association (Queries and Minor Notes, 103:701, 1934), "... most high carbohydrate foods of the artificial and refined types are lacking in the basic elements. These basic ions, such as sodium, potassium, and calcium, are necessary for the neutralization and excretion of the various acid waste products of the body. Hence carbohydrates may be implicated in the occurrence of such an acid state by displacing other necessary food products from the dietary."

Ordinary cereals and cereal products, meat, and eggs—all produce an acid ash when burned in the body, yet they form the mainstay of the average diet. Although this preponderance of acid-forming foods is not definitely known to have great significance for the health of normal adults, a number of authorities advocate a basic or alkali-forming diet for children and pregnant women.

INFANCY AND CHILDHOOD. "Alkaline diets are essential for infancy where growth is rapid," declares Shohl. He calculates the need as 10 c.c. excess of 0.1 normal base per kilo day.[1] Babies fed on breast milk stored an excess of base over acid, the range being from 31 to 56 c.c. 0.1 N base per day, is the finding of the Committee on Growth and Development of the White House Conference on Child Health.[2] Lippard and Marples observed greater increases in weight of infants receiving basic diets as compared with controls on acid-forming feedings.[3]

PREGNANCY AND LACTATION. Shohl states, "Pregnancy and lactation require additional alkali—a minimum of 150 c.c. of 0.1 N base per day."[1] Coons and associates, from acid-base balances taken upon normal pregnant women receiving basic diets, determined that the storage of basic substances was even greater than estimated by Shohl. "This may be some indication," they say, "of the magnitude of the maternal needs exclusive of fetus."[4]

As the chief alkali-forming foods are fruits, vegetables, and milk, the ordinary basic diet consisting of these foods is likely to be low in calories and often does not appease hunger. But Pablum—the only base-forming cereal*—offers a way to add muffins, cereal, puddings and similar "filling" foods to the usual basic diet. Pablum, moreover, is richer than ordinary cereals in calcium, phosphorus, iron, and copper and supplies vitamins B and G.

[1-4] *Bibliography on request.* *Mead's Cereal (Pablum in uncooked form) is also base-forming.

MEAD JOHNSON & COMPANY, - - - Evansville, Indiana, U.S.A.

Pablum (Mead's Cereal thoroughly precooked) is a palatable basic cereal consisting of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa leaf, beef bone, brewers' yeast, iron salt and sodium chloride.

Cereal	Base	Acid
PABLUM	1.8	
Farina		11.0
Oatmeal		12.9
Wheat, whole		11.5
Cornmeal		5.3
Barley		10.1
Rice		8.1

A Study of the Glycemic Response in Patients With Biliary Tract Disease*

By

HENRY A. RAFSKY, M.D., F.A.C.P.†

NEW YORK, NEW YORK

BILIARY tract disease is undoubtedly, more common in diabetics than non-diabetics. This fact has been stressed by Warren (1), Joslin (2), Boyd (3) and many others. While it is generally recognized, that these two diseases are frequently associated, a difference of opinion still exists as to the etiological rôle which gall tract disease plays in diabetes mellitus. Duncan (4) regards the former as a frequent forerunner of diabetes. Mosenthal (5) has pointed out, that the management of gall stones and their complications, with a view to effective prevention of damage to the carbohydrate tolerance has received scant attention. Joslin (2) again, in his most recent work on this subject, stated that we can no longer assign to gall bladder disease a primary causative role in diabetes. Boyd (3) expressed the view that gall stones are more likely the result of the metabolic disturbance rather than, in any sense, a cause of the disease.

The underlying cause of the disturbed carbohydrate metabolism and the explanation for the marked and lasting improvement in the diabetes, which sometimes follows gall stone operations, are also debatable points, resulting from the frequent association of biliary tract disease and diabetes. Jordan (6) regards this improvement in the sugar tolerance, in the same category, as that observed, following the treatment of any active infection, such as a carbuncle. Rabinowitch and Bazin (7) reported some cases of cholelithiasis, with hyperglycemia, in which decreased blood sugar levels, were observed, after operation. They thought that chronic pancreatitis was the cause of the decreased glucose tolerance and that, in these cases, exploration of the common duct, in addition to cholecystectomy, was advisable. Lande and Pollock (8) again, cited their cases of biliary tract disease, with hyperglycemia as well as the case reports of other observers, in which improvement in the diabetes followed gall tract operations, to show that there was a correlation between the disturbance of the carbohydrate metabolism and the degree of impairment of hepatic function. Jacobi (9) also cited his cases, to emphasize the relation of liver damage to hyperglycemia, in obstructive jaundice, due, amongst other affections, to gall stone diseases.

In view of the above, it was deemed of interest to study the glycemic response, in a series of non-diabetic patients, with and without biliary tract disease. The incidence of hyperglycemia was noted in these patients, as well as the effect of surgical and non-surgical measures upon the carbohydrate tolerance. These blood sugar findings were then compared with those observed in the patients comprising the control group.

A series of one hundred and nine patients, ranging in age from twenty-one to fifty-seven years, was studied. The duration of their symptoms varied from eight months to fifteen years. The patients were grouped as follows:

1. Fifty-nine patients with gall stone disease.
2. Fifty patients with abdominal symptoms due to affections other than biliary tract disease. These patients comprised the control group.

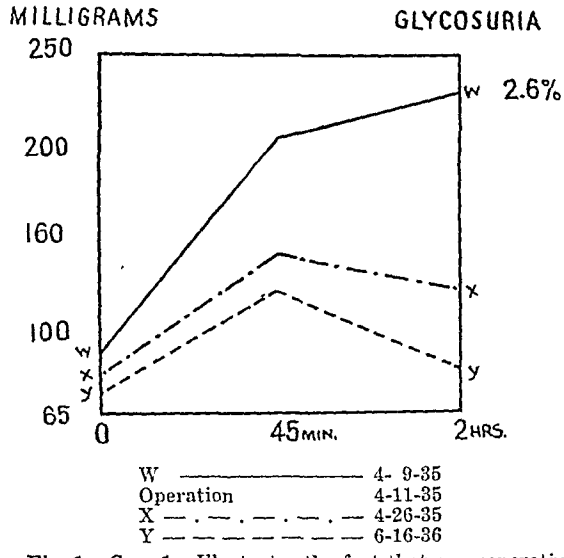

Fig. 1. Case 1. Illustrates the fact that a preoperative hyperglycemic response was followed, after cholecystectomy, by a restoration of the normal glucose tolerance. Mrs. M. S., 39 years old, white, married, complained of attacks of abdominal pain for five years. Operation 4-11-35: Cholecystectomy for calculous cholecystitis; right lobe of liver involved in an extensive fibrosis; left lobe normal.

METHOD OF PROCEDURE

Specimens of blood were obtained for the glucose tolerance test, while the patient was fasting, at forty-five minutes and two hours after the ingestion of one hundred grams of glucose. The determination of the blood sugar was carried out, according to the Benedict Copper Method (10), which places the normal fasting blood sugar between 65 to 100 milligrams in one hundred cubic centimeters of blood. In the patients, who were subjected to operation, the glucose tolerance test was performed prior to and at periodic intervals after surgical intervention. The ingestion of carbohydrates was not restricted before the operation, irrespective of the blood sugar levels. After the operation, the usual post-operative diets were given.

*Read at the New York Academy of Medicine before a Combined Meeting of the Section of Medicine and the New York Gastro-Enterological Society, November 17, 1936.

From the Einhorn Clinic, Medical and Surgical Divisions of the Lenox Hill Hospital, and [illegible] Surgical Divisions of the Beth Israel [illegible]

†Attending Gastro-Ente [illegible] Associate Gastro-Enterologist, Lenox Hill Hospital.

Submitted January 12, 1937.

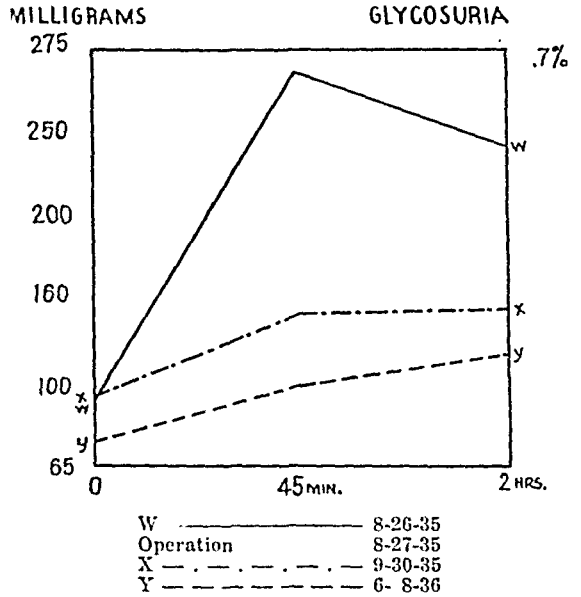

Fig. 2. Case 2. Illustrates the fact that a preoperative hyperglycemic curve was followed, after operation, by normal blood sugar levels, but the curves were not of a normal type. Mr. L. S., 46 years old, gave a history of biliary tract disease of ten years duration. Operation 8-27-35: Cholecystectomy for calculous cholecystitis. The cystic duct was rather long and extended almost to the Ampulla of Vater. The liver was the seat of a fibrosis around the gall bladder bed.

In order to eliminate, in so far as it was possible, the systemic role of infection, the blood for the glucose tolerance test was obtained, while the temperature, blood count and sedimentation rate were within normal limits. Patients with malignancy, jaundice or hyperthyroidism were excluded from this investigation, because hyperglycemia is often encountered in these diseases.

TYPES OF BLOOD SUGAR CURVES OBSERVED

The types of blood sugar curves which were observed during the course of this study were as follows:

A. A normal blood sugar curve.

B. A curve with a normal fasting blood sugar, a continued upward trend beyond 160 milligrams reaching the peak at forty-five minutes and then a return to a normal or almost normal blood sugar level at the end of two hours.

C. A flat curve which was characterized by a normal fasting blood sugar level and with little or no fluctuation, until the end of two hours. This type of curve is often seen in endocrine dysfunction.

D. A curve with a normal fasting blood sugar level, a gradual rise beyond 160 milligrams reaching the peak at the end of forty-five minutes and then a slight descent to the end of two hours.

E. A curve with a normal fasting blood sugar level, a continued upward trend beyond 160 milligrams, reaching the peak at forty-five minutes and then a flat curve from this point on, until the end of two hours.

F. A curve with a normal fasting blood sugar level, then a gradual rise beyond 160 milligrams, with the peak being reached at the end of two hours.

A blood sugar curve of the type B, D, E and F, was regarded as a hyperglycemic response. The average fasting blood sugar level observed in this study was 81 milligrams in 100 cubic centimeters of blood, the lowest being 64 and the highest 97 milligrams. The highest blood sugar level reached after the ingestion of the glucose was 273 milligrams in 100 cubic centimeters of blood.

CLINICAL STUDY

Group 1. This group comprised fifty-nine patients with gall stone disease, ten of whom were males and forty-nine females. In fifty-two of the patients who were operated upon, the glucose tolerance test, preoperatively, revealed the following: A hyperglycemic response in thirty-two patients (61.5%); a normal blood sugar curve in seventeen (32.7%) and a flat curve in three patients (5.8%).

Of the thirty-two patients with evidence of a decreased glucose tolerance, the preoperative glycemic response showed the following: A type "B" curve in eight patients (25.0%); a type "D" curve in eleven patients (34.4%); a type "E" curve in six patients (18.8%); a type "F" curve in seven patients (21.8%).

In twenty-five of the thirty-two patients with a preoperative hyperglycemic response, a definite improvement resulted in the glucose tolerance after the operation, regardless of whether cholecystectomy alone, or cholecystectomy together with choledochotomy were performed. This improvement was observed from two weeks to six months or more after the operation. In five patients the sugar tolerance test did not show any material change after operation. The postopera-

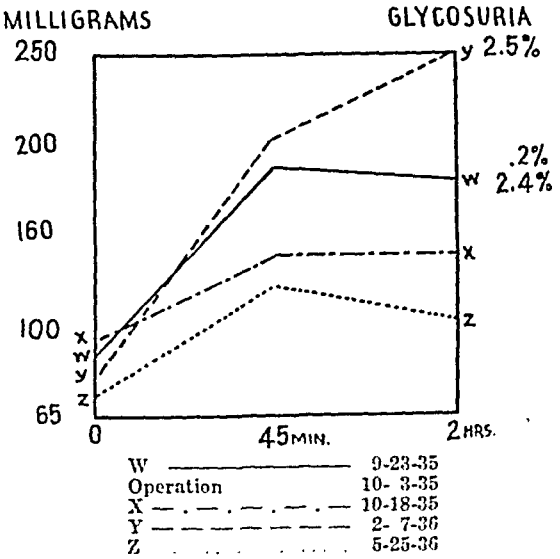

Fig. 3. Case 3. Illustrates the fact that a preoperative hyperglycemic response was followed, after operation, by a reduction in the blood sugar levels, although the curve was not a normal one. Several months later, further evidence of a decreased tolerance was observed. The patient, who was five feet tall, weighed 70 kilograms. She was placed on a diet composed of carbohydrate 185 grams, protein 85 grams and fat 50 grams. An improvement in the glucose tolerance was then observed, both in the blood sugar levels and type of curve. Mrs. P. D., 55 years old, white, married, gave a history of attacks of biliary colic on and off for ten years. Operation 10-7-36: Cholecystectomy for calculous cholecystitis. The common duct, which was dilated, was explored but no stones were found. The liver was enlarged.

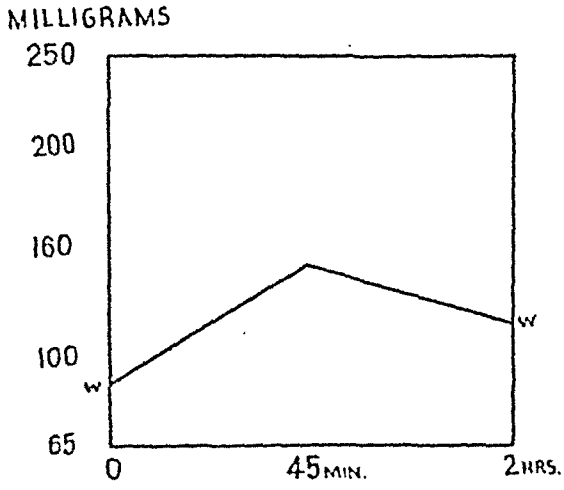

Fig. 4. Case 4. Illustrates the fact that a comparatively normal blood sugar curve may be present in a patient, with gall stone disease with marked pancreatic involvement. Mrs. S. B., 33 years old, white, married, gave a history of attacks of pain in upper right quadrant, on and off, for six years. Operation 5-7-35: Cholecystectomy was performed for calculous cholecystitis. The fat of the falsiform ligament as well as omentum and all retroperitoneal tissues were studded with fat necrosis as a result of an acute pancreatitis. Palpation of pancreas showed it to be thickened, hardened and swollen. Numerous stones were present in the gall bladder. The liver was large and soft.

tive improvement, which was noted in the twenty-five patients was as follows: In fourteen patients there was a complete restoration of the normal carbohydrate tolerance. In four patients the blood sugar levels were within normal limits but the curves were not of a normal type. Two of these four patients, who were over weight, subsequently showed further evidence of a decreased glucose tolerance. They were placed on a high carbohydrate low fat diet, which Rabinowitch (11) has termed a "high carbohydrate, low caloric diet." Following this regime an improvement was noted in both the blood sugar levels and the type of curve. In four patients the curves had a more normal trend but the blood sugar levels, although lower, were not within normal limits. In three patients there was a postoperative restoration of the normal tolerance within three months but after a return of the abdominal symptoms, a hyperglycemic response was again observed. After the patients became symptom-free, normal blood sugar curves were found.

In two patients who returned, after cholecystectomy, complaining of diarrhea, loss of weight and weakness, a flat blood sugar curve was observed. As this type of blood sugar curve is often encountered in hypothyroidism, hypopituitarism, hypoadrenalism and ovarian dysfunction, it was deemed advisable to treat these patients on an endocrine basis. Following this plan of therapy a clinical improvement and normal blood sugar curves were noted.

A blood cholesterol was determined in twenty-one of the thirty patients with a preoperative hyperglycemic response. The average blood cholesterol reading was 197 milligrams in 100 cubic centimeters of blood.

Group 2. The control group comprised fifty patients who were suffering from affections such as inguinal hernia, chronic appendicitis, nephrolithiasis, peptic ulcer, constipation and fibroid of the uterus. Fourteen of the patients were males and thirty-six were females.

A normal blood sugar was found in thirty-nine patients (78.0%) of the control group. In the remaining eleven patients (22.0%) a hyperglycemic response occurred. A type "E" curve was observed in one of these patients and a type "B" curve was found in ten patients. Amongst the eleven patients in the control group to give a hyperglycemic response were eight, suffering from peptic ulcer. Altogether fifteen patients with peptic ulcer were studied.

At times it was observed, in both the gall stone patients as well as those in the control group, that the glucose tolerance test immediately after operation showed an increased blood sugar curve as compared to the glycemic response present before operation. This postoperative decreased glucose tolerance, could be accounted for on the basis of an intercurrent infection such as a broncho-pneumonia or surgical reaction. Within a period of three months, the glucose tolerance test, in these patients, again showed normal blood sugar curves.

The following case reports will illustrate the varied clinical phenomena which were observed during the course of this study.

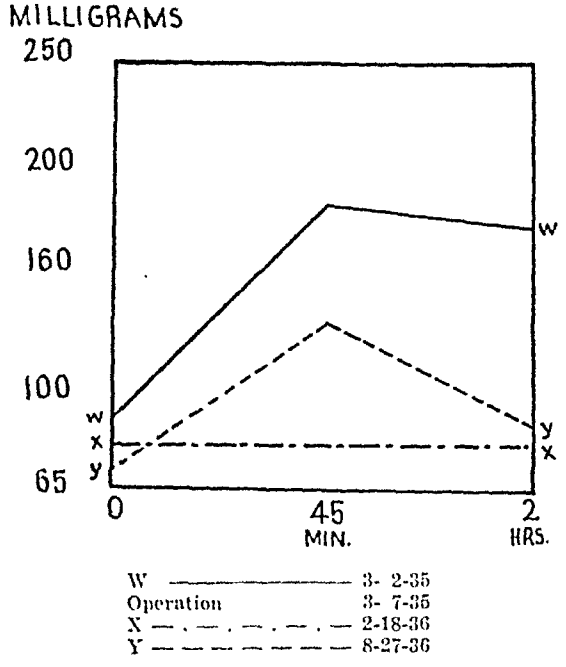

Fig. 5. Case 5. Illustrates the flat type of blood sugar curve in a patient, who complained of nervous and abdominal symptoms without severe pain, after cholecystectomy. Mrs. H. G., 41 years old, white, married, had a cholecystectomy performed for a calculous cholecystitis. She returned about one year later complaining of epigastric distress, a choking sensation, diarrhea, insomnia and a loss of fifteen pounds in weight. The patient was treated on the basis of an ovarian dysfunction. Lutein was administered parentally three times a week. About six months later a normal blood sugar curve was found; the patient had gained ten pounds and was comparatively symptom free.

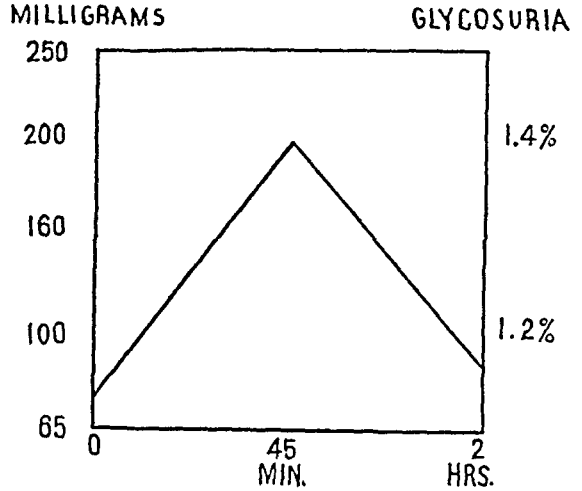

Fig. 6. Case 6. Illustrates the type of curve seen in patients with peptic ulcer and a hyperglycemic response. Mr. H. S., gave a history of duodenal ulcer of eight years duration.

DISCUSSION

A comparative study of the blood sugar levels was made in patients with and without biliary tract disease. It was found that a hyperglycemic response was present in 61.5% of the fifty-two patients with gall stone disease, who came to operation and in only eleven (22.0%) of the fifty patients in the control group. Surgical intervention resulted in an improvement of the carbohydrate tolerance in most of the patients in Group 1, although an improved glucose tolerance, after operation, did not always signify a normal type of curve. In two of the cholecystectomized patients a high carbohydrate low fat diet was employed to influence the blood sugar index and the type of curve. This was illustrated in Case 3. In two patients with nervous and abdominal symptoms and a flat blood sugar curve, after cholecystectomy, an attempt was made, as was illustrated in Case 5, to influence the clinical course and the glycemic response by the use of endocrine therapy.

The types of curves observed in Groups 1 and 2 have been outlined. In this connection it is interesting to note that in all of the ulcer patients with a hyperglycemic response, a type "B" curve was observed. Although penetration into the pancreas is not an infrequent complication of peptic ulcer, still, the association of peptic ulcer and diabetes is comparatively uncommon. Jordan (12) found one case of glycosuria and high blood sugar curves present in 351 cases of peptic ulcer. Eustermann and Balfour (13) also stressed the rare occurrence of glycosuria in gastric and duodenal ulcers. Therefore a hyperglycemic response with a type "B" curve cannot be regarded as definitely pathological in its relation to a disturbed carbohydrate metabolism, as the other types of curves which were found in most of the patients in Group 1.

Various explanations may be advanced, to account for the decreased glucose tolerance in many of the gall stone patients in Group 1, and for the improvement in the glycemic response found in most of the patients, after surgical intervention. To attribute these phenomena, solely to the mere presence and treatment of an active infection, somewhere in the body, is unsatisfactory. For, in this study, an attempt was made, in so far as it was possible, to rule out the systemic rôle of infection. Until recently, pancreatic dysfunction was regarded as fundamentally important in causing a disturbed carbohydrate metabolism. But, as a result of the work of Mann and Magath (14), Soskin and his co-workers (15, 16), it appears that the liver is the probable determinating factor in regulating the blood sugar levels, after the ingestion of glucose. Mattina (17) observed, that in dogs, hyperglycemia was a constant finding in experimental stenosis and occlusion of the common bile duct. He stated that the increase in the blood sugar index, both in height and rapidity of development, varied according to the diversity of the liver changes, which were produced in these cases. Canterow (18) has emphasized the fact that hepatic functional impairment is frequently found in apparently uncomplicated gall bladder disease.

The varied clinical phenomena, observed in this study, some of which were illustrated in the case reports, would tend to point to hepatic rather than pancreatic involvement, as the underlying cause of the disturbed carbohydrate metabolism. It is also reasonable to assume that the postoperative improvement in the glucose tolerance, which was noted in most of the gall stone patients, was due to improved liver function. But it must also be admitted that in long standing biliary tract disease, the pancreatic rôle as a cause of the increased blood sugar levels, cannot be entirely eliminated, as, under these circumstances, degeneration of the islets of Langerhans may eventually take place.

SUMMARY

A decreased glucose tolerance was observed more frequently in non-diabetic patients, with gall stone disease, than in those without this affection.

The type of curve observed in most of the patients with a hyperglycemic response, in the control group, was different from that found in the majority of the patients with cholelithiasis.

Surgical intervention, resulted in an improvement in the glucose tolerance, in most of the gall stone patients.

The varied clinical phenomena observed, pointed to a hepatic dysfunction, rather than a pancreatic impairment, as the probable underlying factor in the disturbed carbohydrate metabolism.

CONCLUSIONS

1. Cholelithiasis, in non-diabetic patients, is a comparatively frequent cause of a disturbed carbohydrate metabolism.

2. The early removal of the gall stones will probably lessen the incidence of diabetes mellitus in these patients.

Studies on the Neutralization Test of Gastric Acidity in Relation to General Disease*

By

KENNETH PHILLIPS, M.S., M.D.

MIAMI, FLORIDA

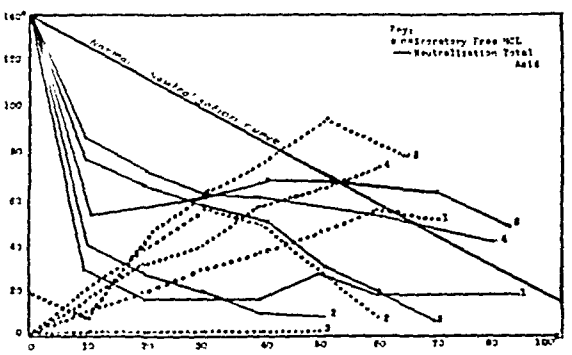
THE value of analysis of gastric contents in the study of ulcer has long been considered of great significance. More recently attention has been turned, especially among clinicians, to its value in the pathogenesis, diagnosis and treatment of other gastro-intestinal syndromes as well as disease in general. The result of this expansion in thought has been the appearance of periodical reports such as those of Haden (1), Apperly (2), Murry (3) and others dealing with the relationship between a gastric factor and certain types of blood dyscrasias and Christie's (4) suggestion of the etiological relationship between achlorhydria and many of the deficiency syndromes. Clinical study of the gastric secretory function, in spite of the vast amount of investigation, has proven to be, to a great extent, variable and disappointing. The various reasons for this are well understood and have been extensively discussed.

The experimental work of Mirai, Boldyreff (5), MacLean and Griffiths (6), Mathews and Dragstedt (7) and many other investigators showing the definite ability of the contents of the normal stomach to neutralize hydrochloric acid when introduced in physiological concentration (0.5 per cent) has been observed with keen interest. Within the past two years Elman and McLeod (8) and Levy (9) have, undoubtedly, established the clinical application of the above experimental work to ulcer. They have properly given to this clinical application a name "the neutralization functional test of the stomach." The physiological basis for this function of the gastric contents, together with the possible clinical value, including the details of technique, are discussed so thoroughly and extensively in both reports that they need not be reiterated here. Both reports are most convincing, both limited, however, to the study of the neutralization test in relation to peptic ulcer, Levy reporting in addition its application to pylorospasm and chronic appendicitis. The call for more extensive work and broader application of the test so frankly emphasized by these investigators is self evident.

This study and report is an attempt further to confirm the work reported by these observers and in addition to modify their technique, if possible, in order that it becomes more practicable from a standpoint of simplicity especially to the individual clinician not in possession of an associated laboratory equipment whereby it is distinctly to his, as well as his patient's, advantage to be able to complete both the secretory and neutralization studies at one sitting. Since the clinical reports of Elman and McLeod and Levy are so convincing in relation to peptic ulcer, pyloric obstruction and possibly chronic appendicitis, it becomes self evident that we should attempt to determine whether or not its clinical value is limited to these conditions alone or if the test also possesses value not only in other diseases of the gastro-intestinal tract but in some diseases not primarily associated with the tract such as those of allergic nature.

MODIFICATION OF TECHNIQUE

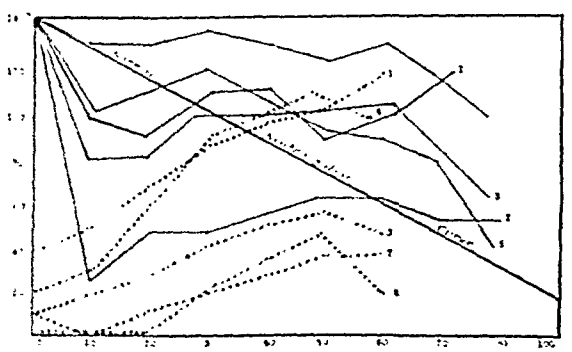
The technique described by Elman, McLeod and Levy consists of passing a small duodenal tube, the same as for the fractional gastric analysis, emptying the stomach by aspiration then instilling 300 c.c. of 0.5% (Elman) or 0.6% (Levy) HCl into the stomach; aspirating small specimens at ten to twenty minute intervals for seventy to one hundred twenty minutes; titrating with tenth normal sodium hydroxide and plotting a fractional curve. These tests were made separately from their comparative secretory fractional Ewald meal determinations on the same patients.



The modification offered here is concerned with further simplifying the technique which renders its application to the individual clinician more feasible. In the first place it is well recognized that mechanical distention of the stomach from any fluid may act as a stimulus. Therefore, if the total volume used can be reduced, the results are likely to be more accurate. This can be accomplished by shortening the time intervals of aspiration to ten minutes and the fractional volumes to 10 c.c. each. It is then necessary to use only one hundred fifty to two hundred c.c. of the 0.5% HCl. A second aggravating factor to the accuracy of the test is also eliminated by this reduction in volume

*From the Department of Medicine: James M. Jackson Memorial and Victoria Hospitals.

Submitted October 8, 1936.



namely, the nervousness from distention even with vomiting which has been so common in our experience with the larger volumes.

It is, of course, obvious that fractional secretory curves are desirable for comparison in all cases. It has, undoubtedly, been established that a secretory test meal consisting of seven per cent alcohol is equally accurate, if not more so, than the Ewald meal. Since this is a liquid meal it is possible to theoretically, at least, empty the stomach after the secretory curve has been obtained. Then, if the subsequent introduction of the 0.5 HCl will produce curves which conform to those established by Elman and Levy, we now have a technique whereby both curves can be obtained at a single intubation. Furthermore we also now obtain both curves under the same physiological and psychological conditions both of which can easily change from time to time and both of which, undoubtedly, affect the accuracy of the tests when performed separately. Reference to Figure 1, Graph I and II reveals that these modifications can be accomplished with sufficient clinical accuracy in both normal and ulcer patients. While there is apparently a slight lagging in the beginning of the neutralizing curve for possibly the first ten minutes it then assumes a course similar to that established by Elman and Levy. This slight inaccuracy is soon overcome by experience in

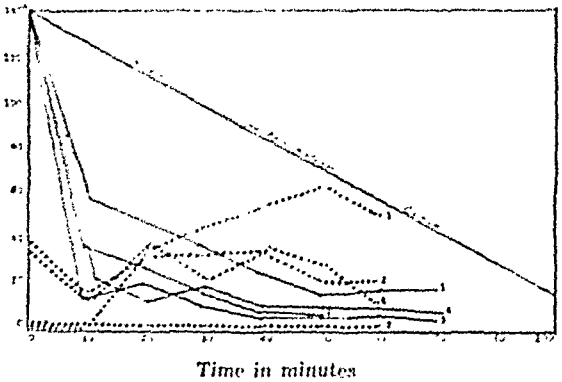
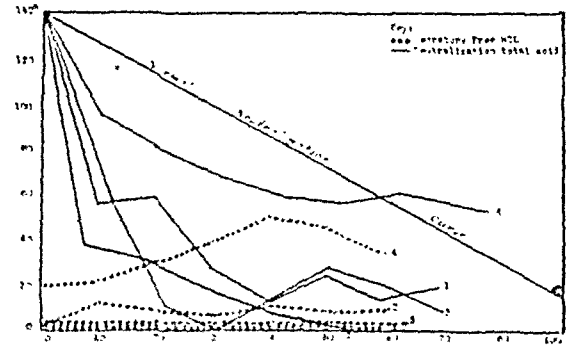
one's individual interpretations which have to be developed gradually in either case.

METHOD OF STUDY AND RESULTS



Five normal healthy individuals (volunteers) and five cases with duodenal ulcer confirmed clinically and by X-ray findings were selected and exposed to fractional gastric secretory analysis using seven per cent alcohol as the test meal. At the completion of the secretory test the stomach was emptied and one hundred fifty to two hundred c.c. of 0.5% HCl immediately instilled and the aspirations continued at ten minute intervals. It will be noted upon reference to Figure 1 that both groups present graphic curves which conform closely in general type to those established by Elman and Levy. Two important facts, however, must be kept in mind. The gastric power to neutralize in normal individuals is quite variable except that in our experience we have never found it to be delayed above the normal curve line established by Elman. In many cases, however, it is markedly increased, the curve assuming a sharp drop even to the zero or base line. We studied the curves in over thirty cases in order to be certain that this variation is correct. The second fact which has come to our observation is in the ulcer case (confirmed by clinical and X-ray studies) with an associated absence of free hydrochloric acid during the secretory meal. The

neutralizing curves in these cases assume a sharp downward course and fail to reveal the usual delay shown in the other ulcer cases. Two such curves are shown in the graphs of Elman and McLeod (7) but they were in cases following gastric resection and, therefore, do not cast helpful light upon the explanation. In this series we were unusually fortunate in being able to study two cases, (1) and (2) illustrated in Figure 2, Graph I. Case (1) possessed a large duodenal ulcer involving the major portion of the cap while case (2) presented the most extensive ulceration of the gastric lesser curvature we have ever observed. Curious enough the emptying time of the stomach in both cases was much more rapid than normal, therefore, it is safe to assume that no pyloric obstruction was present in either case. Just at the time we were studying these two cases a fortunate coincidence occurred in that there appeared two cases of carcinoma, one primary in the stomach with a palpable mass, the other metastatic, secondary to a breast malignancy (both were confirmed at autopsy). Both were extensive in invasion and were producing pyloric obstruction with retention and vomiting in one case. Studies of the secretory and neutralizing curves as compared to the achlorhydria ulcer curves are most interesting since it will be seen (Figure 2, Graph II) that the secretory functional curves are at the upper normal level while the neutralizing curves assume a sharp drop almost identical with the ulcer curves in Graph I.



Time in minutes

Fig. 4. Graph II. Secretory and neutralization curves of Pellagra (Case 1) and chronic appendicitis with ovarian cyst (Case 2). Note marked increase in neutralizing power in Case 1; delayed in Case 2.

This observation, I feel, is very important from the standpoint of analysis and interpretation. I suppose it is correct that one should never venture an opinion without unquestionable basic facts; but after three years of experience and study in these curves in every case who has been exposed to gastric analysis, I am more and more of the opinion that there is some mechanism entering into this neutralizing function other than the regurgitation of duodenal contents into the stomach. In the two ulcer cases the pyloric opening was probably even more relaxed than in the normal because the emptying time was so rapid. Regurgitation, therefore, of duodenal contents could be more accessible which might contribute to both achlorhydria and increased neutralizing power. However, in the carcinoma cases there was marked pyloric obstruction and while they manifested notably high secretory curves for malignancies, the neutralizing curves assumed the almost identical course of the ulcers. There is only one factor which these cases share in common, that of extensive pathological involvement. In one of the ulcer cases almost half of the entire distal end of the lesser curvature was involved, in the other nearly two-thirds of the cap. In both of the malignancies the involvement was extensive. Why the increase in neutralizing power in the presence of pyloric obstruction whereby the regurgitation of duodenal juices is re-

duced? Is it not suggestive that the stomach itself might possess some neutralizing function which might be inhibited under some conditions, stimulated under others?

GASTRO-COLONIC SYNDROME GROUP

An attempt is made to classify, as a group, eighteen cases of this type so familiar to every internist. The complaint is a vague indifferent form of sub-acute or chronic indigestion with gaseous distention often hinging upon some foreign foci of irritation or infection in the upper respiratory or genito-urinary tracts. These cases are usually organically negative throughout the gastro-intestinal pathway except for spasm of the colon and very often associated pyloro-spasm under the barium meal. The eighteen cases fell into the following groups: Chronic spastic colon with mucus, three; spastic colon without mucus, five; psychoneurosis, two; chronic follicular tonsillitis, four; chronic bronchiectasis, one; genito-urinary pathology, three. Studies of the secretory and neutralizing curves (Figure 3, Graph I) reveal them to be so variable and inconstant as to be entirely unreliable. However, those variations are within what would be obtained in any normal series of patients. They do demonstrate, however, the remarkable constancy of the power of gastric contents to neutralize free hydrochloric acid and also that this neutralizing curve assumes its own course independent of the secretory curve. These facts are clearly demonstrated in cases one and two of the graph. The neutralization functional test then in cases of chronic gastro-colonic indigestion are apparently of no value as a diagnostic aid.

LIVER AND GALL BLADDER DISEASE

Eight cases of liver and gall bladder disease all confirmed at subsequent operation or autopsy were exposed to both secretory and neutralization tests. Gall stones were present in three, hepatitis and gall bladder disease without stones in four and hypertrophic cirrhosis in one. All cases manifested an associated indigestion with some upper abdominal distress and one case, shortly after the study, was erroneously explored for perforated ulcer. In all cases while the secretory chemistry varied, there was a definite increased neutralization power as shown by the curves. Graph II in Figure 3 illustrates some of the curves. Since this is the direct opposite tendency to that found in ulcer and pylorospasm, it suggests a definite differential diagnostic test even though eight cases are not enough to substantiate conclusions.

ALLERGIC DISEASE

It was reasonable to presuppose that something of value would likely result from a study of allergic individuals especially those harboring a definitely proven food allergy. Thirty-two such cases were selected, being composed of chronic urticaria, eight; perennial hay fever, two; Migraine, one; chronic generalized eczema, three; and bronchial asthma, eighteen. All cases were proven to manifest aggravation of symptoms by certain foods or gastro-intestinal stasis. Secretory and neutralization studies were then carried out and, while the secretory chemistry fluctuated considerably with a surprising number showing achlorhydria, the neutralization curves were all within normal limits with some tendency toward an increased neutralizing power. One case ((1) Figure 4, Graph I) is of particular interest since upon the first study she showed complete achlorhydria with increased neutralizing power. Eight months later her secretory curve returned to a high normal but the neutralizing curve remained practically identical with that of the first.

MISCELLANEOUS GROUP

Thirteen cases representing different diseases but manifesting in association some indigestion and abdominal complaint, were chosen and studied. They included Acne Rosacae, one; Undulant fever, one; chronic generalized Psoriasis, one; Pellagra with diarrhea, one; essential hypertension, one; chronic appendicitis and ovarian cyst, one; tuberculosis (incipient, renal and intestinal), three; hypertrophic arthritis, four. Nothing of diagnostic value was revealed in either the secretory or neutralization curves except in the case of pellagra (Figure 4, Graph II, Case 1) in which the neutralization curve sharply dropped to zero in ten minutes and in the case of chronic appendicitis and ovarian cyst, confirmed by surgery, (Case 2) a neutralizing curve which was delayed and similar to those established by Levy.

GENERAL DISCUSSION

At the beginning of this study it was thought that a more or less untried test of gastric or gastro-duodenal function, namely the power of the stomach to neutralize 0.5% HCl when instilled into its lumen, may be of diagnostic or pathogenetic clinical value in disease in general or at least gastro-intestinal conditions other than spasm or ulcer as already established by Elman and McLeod and Levy. Especially might this be expected in allergic disease where food and gastro-intestinal upsets definitely produce or aggravate the symptoms. This study and report fails to confirm the original thought, except in cases of liver and gall bladder disease, where it has shown in a small group of proven cases that there is apparently an increased neutralizing power of the stomach, which, if confirmed, will serve as a valuable diagnostic aid since it was constant whether or not stones were present. The marked increase in neutralizing power in the case of Pellagra suggests further work as to its value in other deficiency diseases since recent reports are appearing which suggest a gastric factor in these diseases.

It is evident that the automatic regulation of acidity by the stomach is becoming one of the most important problems of physiology and gastric pathology. Since the original work of Heidenhain and Pavlov many theories have been advanced. There is no agreement as yet, and three or four opposing views exist in recent literature. Undoubtedly, the original physiological work was stimulated by the question, "Why does not the stomach digest itself?" This would be a logical question to follow the monumental work of Claude Bernard in 1856.

Modern views of the mechanism of neutralization include: (1) cessation or inhibition of HCl secretion, (2) acceleration of the emptying time of the stomach with associated secretion of a less concentrated juice, (3) mucus and acid binding substances, (4) alkaline secreted gastric juice, (5) duodenal regurgitation, (6) resorption of the secreted or introduced HCl by certain portions of the stomach.

Of these various views, undoubtedly, the most widely supported is that of regurgitation of duodenal contents. This theory was first sponsored by Boldy-

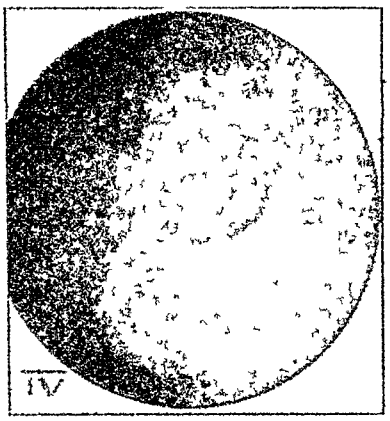

Fig. 1 is that of a single polyp.

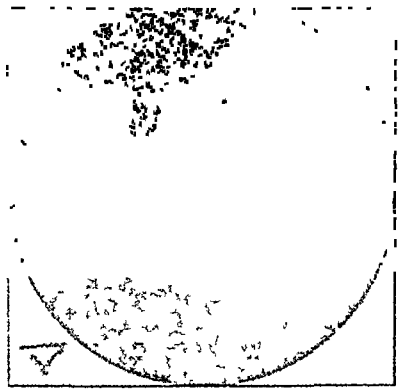

Fig. 5 shows multiple polypi, an unusual finding in the stomach. (Thanks are given to Dr. Wallace for this print).

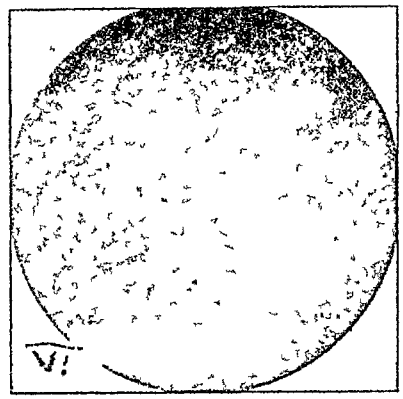

Fig. 6 shows many small erosions or ulcerations.

diagnosis, a more enlightening concept of living pathology as shown by photography is placed at the physician's disposal. It does not seem as yet advisable to speak of percentages of correct diagnosis in evaluating the benefits to be derived from the use of this procedure. The author is inclined rather to confine himself to the criteria for diagnosis, the pitfalls to be avoided and the possibilities for aid to be derived therefrom. In studying the gastric mucosa, one must remember that he is looking at photographic impressions produced by the elevations and depressions within it. The size of the deformities and irregularities seen on the completed prints are roughly, one-half the actual size. The trained physician familiar with the morphologic appearance of the normal mucosa, readily recognizes (the appearance of the rugal folds in the photograph) as they course along the stomach wall. They are higher, more compact and more numerous on the lesser curvature and flatter and sparser in other areas. An abrupt and even gradual departure from the normal becomes apparent and diagnostic conclusions readily drawn. The author presents eight photographs which demonstrate certain observations

COMMENT

Intragastric photography now has been used about seven years. Close observation and study by the author over a period of more than six years lead him to continued enthusiasm for the great possibilities of the method in an endeavor to make more thorough diagnosis of gastric lesions. Pathology may be seen on the photographic films which has been missed by X-ray studies. One is better oriented as to the pathologic histology of such a lesion when seen by this method. The possibilities for errors of omission particularly are lessened after the stomach mucosa has been photographed in addition to all other diagnostic procedures used. Its ease of application and the small amount of time consumed (usually less than one minute) makes it more desirable than gastroscopy. Then, too, one can study at leisure the permanent record of what one might more or less fleetingly see by gastroscopy. Progress has been made in the study of the application and value of the method and much more will naturally be learned concerning both the technique and evaluation of what we see, as its use becomes widespread

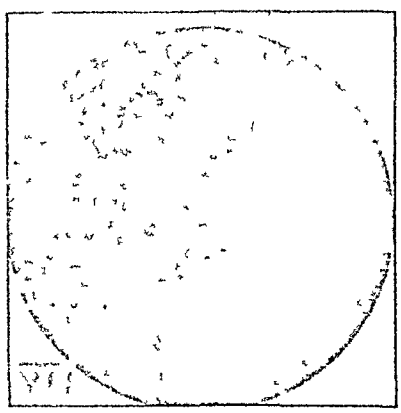

Fig. 7 is a view into and through the pyloric antrum with the pylorus itself in the distance.

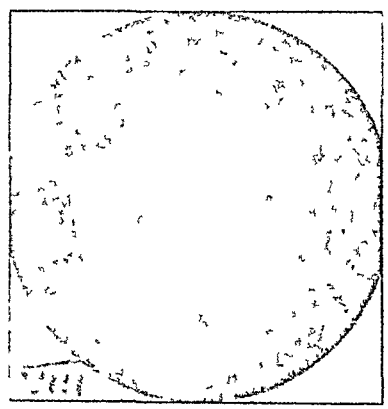

Fig. 8 is that of a hand taken at 2 inch photographic distance to convey some idea of the extent of stomach wall photographed and a comparative study as to the size of objects seen

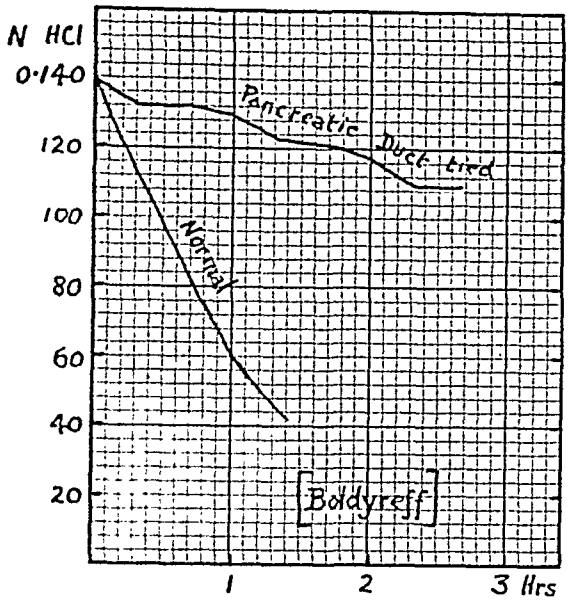

Fig. 1. Showing reduction of acidity when 0.140 N HCl is placed in a dog's stomach (a) under normal conditions, and (b) after ligature of pancreatic duct. (Redrawn from Boldyreff's figures).

delayed reduction of acidity when acid was artifically placed in the stomachs of people who had hyperchlorhydria with the ordinary gruel-meal test (Apperly 1). Fig. 2 shows the gruel-meal acidity curves of a group of eight students, and Fig. 3 shows the results in the same group when 250 c.c. of 0.4% HCl was placed in their stomachs. It will be seen that, in general, those who have high (or low) acidity in the former also have high (or low) acidity in the latter. In other words gastric acidity is a matter of dilution and neutralization rather than of secretion of acid. In the same year Apperly and Cameron (4) showed a similar failure to reduce acid placed in the stomach in cases

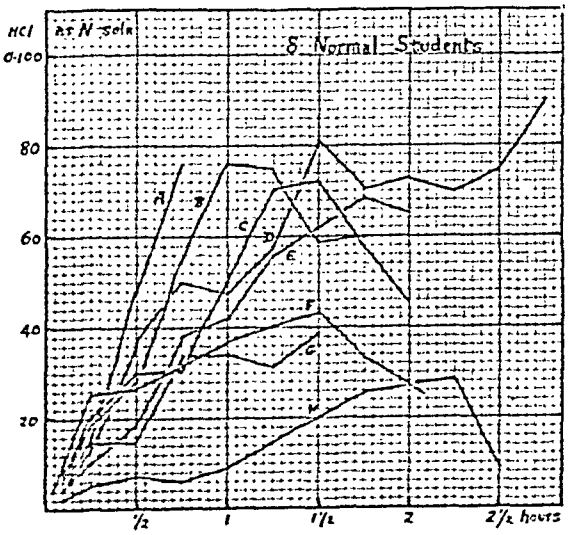

Fig. 2. Fractional test-meal curves (gruel meal) in eight normal students.

of known pancreatic disease (Fig. 4) and first suggested the "acid test" for disease of this organ. Favorable reports concerning this test have since been received. In 1924 I (2) also showed the rapid reduction in the acid test following gastro-enterostomy. (Fig. 5).

Very little further use was made of this test until 1929 when Elman (9) showed that in duodenal ulcer there is some failure to reduce acid in the stomach (Fig. 6—Compare this with Fig. 5). In 1935 he published a further series of cases of duodenal ulcer before and after gastro-enterostomy.

Levy (13) in 1934 showed among other things a diminished acid reduction in cases of chronic appendicitis before operation. (Fig. 7). He believes this failure to reduce acid is due to pyloric spasm. He

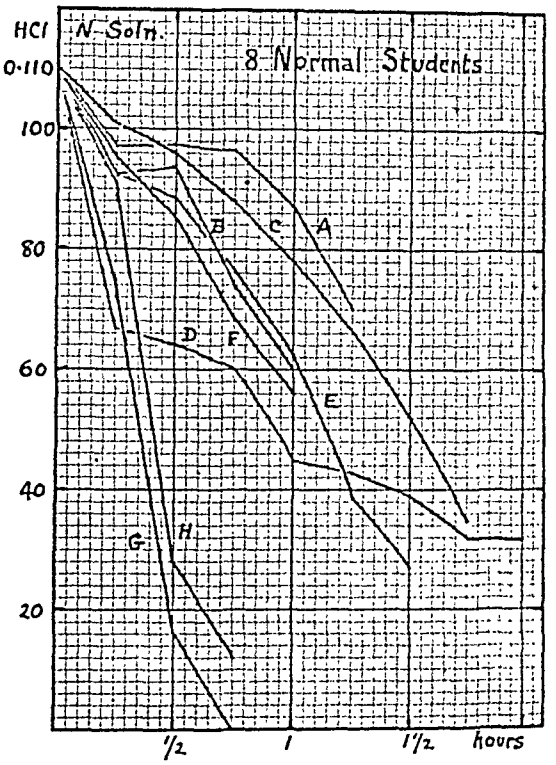

Fig. 3. Showing the fall of acidity in eight normal students (same as those of Fig. 2) when 250 c.c. of 0.110 N HCl is substituted for the gruel meal.

concluded that "as compared with the ..... Ewald test-meal, the neutralization test showed a greater uniformity and in general a closer correlation with the physical and clinical findings and would seem, therefore, to be of greater diagnostic importance."

Various writers have referred to this test as the Neutralization Test. This is a misnomer, since it has been shown by several authors (Apperly (3), MacLean and Griffiths (14) and others) that acid placed in the stomach is reduced almost wholly by dilution, and to only a small extent (and often not at all) by neutralization by duodenal fluids. Hence the term "Acidity Reduction Test" would appear to be better.

One further point should be noted. Most of those

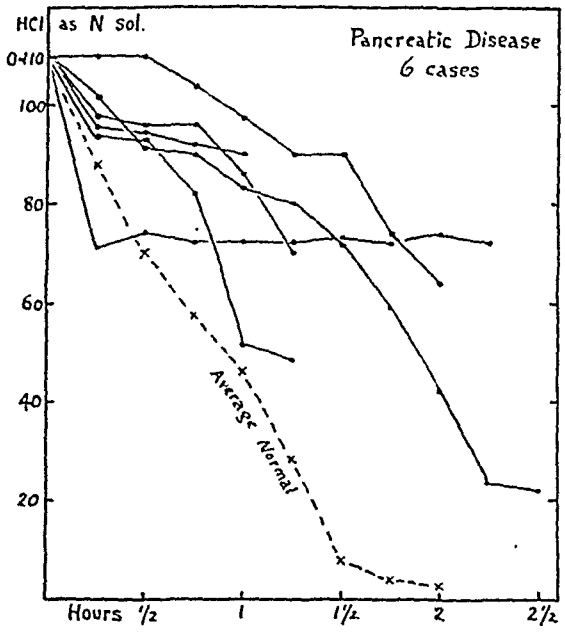

Fig. 4. Acidity Reduction Test in pancreatic disease.

using the test have assumed, following Pavlov (15), Ivy and Whitlow (12), and MacLean and Griffiths (14), that, when acid is artificially placed in the stomach, secretion of hydrochloric acid by the gastric mucosa is suppressed. Generally this appears to be true, but in a certain proportion of cases considerable additional acid may be secreted (Apperly and Norris (7)). In practice, however, this does not seem to vitiate the general results of the test.

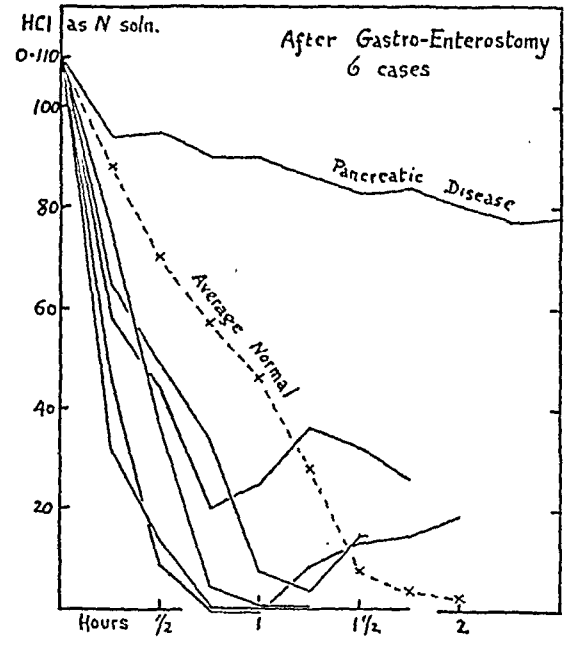

Fig. 5. Acidity Reduction Test After Gastro-enterostomy (one of these cases was found to have pancreatic disease. See Reference 2).

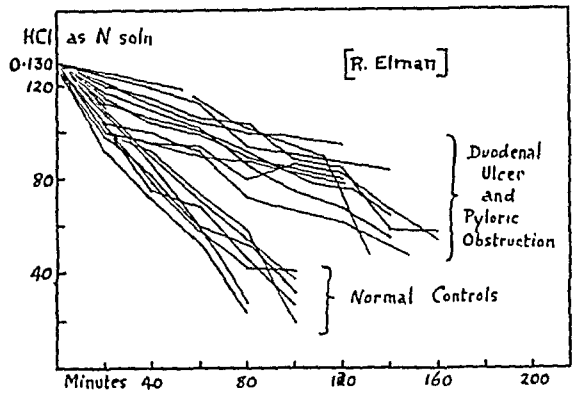

Fig. 6. Acidity Reduction Test in duodenal ulcer and pyloric obstruction. (After Elman (9)).

TECHNIQUE OF TEST

The Rehfuss tube is swallowed by the fasting patient and all fasting contents withdrawn. 250 c.c. of 0.4% (0.110 N) HCl, previously warmed to body temperature, is drawn up into a large (100 c.c.) pipette, which is then attached to the free end of the tube. By holding the pipette above the level of the head, the acid runs into the stomach by gravitation. The test is then conducted as in the usual fractional test-meal, i.e. samples are withdrawn every ¼ hour and titrated for free acid. Insufficient stress however has been laid on one very important point, viz., thoroughly mixing the gastric acid before withdrawing a sample, by moving the piston of the withdrawing syringe back and forth about 6 or 8 times. Experience has shown that this insures a uniform mixture in the stomach.

DISCUSSION

The degree of acidity of the gastric contents does not, of itself, give rise to any sensation. Thus acid, of an acidity far greater than that found in any pathological condition, when placed in the stomach is not in any way appreciated. On the contrary, Hurst (11) has shown that the only adequate stimulus for the production of the sensations of fullness, discomfort and pain in the stomach and intestine is increase of ten-

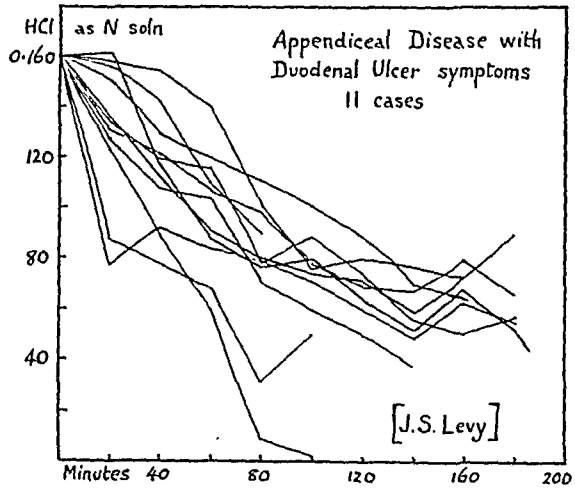

Fig. 7. Acidity Reduction Test in appendiceal disease with ulcer symptoms. (After Levy (13)).

sion or pressure of contents above a certain critical level in that organ. Thermal, chemical, or tactile stimuli, provided they do not cause spasm and rise of tension, are not felt by the patient. This has been shown in operations under local anesthesia.

From the foregoing facts it follows that these symptoms of indigestion can be brought about by such incoordinations of gastro-intestinal muscular activity as give rise to increased intra-gastric or intra-intestinal pressure. Thus a stomach powerfully forcing its contents against a pyloric obstruction gives rise to fullness, discomfort or pain according to the degree of pressure produced.

On the other hand we know from common experience that high or low acidity is often found in certain different forms of indigestion—but not necessarily. In order to clearly understand the relation of acidity to gastro-intestinal muscle function let us consider the series of events following a meal.

When a gruel test-meal is placed in the stomach, hydrochloric acid of concentration 0.174 N (Hollander and Cowgill (10)) is secreted into the fluid food. Usually the acidity rises for one to 1¼ hours and then falls. This fall is brought about chiefly by a regurgitation of duodenal fluids which dilute and to some extent neutralize the gastric acid. The acidity curve can be raised by: (a) increased secretion of acid. (b) increased rate of gastric emptying, which leaves a smaller residue of food to be acidified, thus raising the concentration of the acid, and (c) a diminution or failure of duodenal regurgitation. An opposite set of conditions lowers acidity.

With this double response of the stomach to the introduction of food, viz. 1. acid secretion, and 2. gastro-intestinal movements of flux and reflux, it is obvious that if we could eliminate the former, then any variations in the acidity curve must be brought about wholly by the latter, and so give a much clearer indication of the nature of the faulty gastro-intestinal muscle activity, which is the cause of the symptoms. Hence the origin of the Acidity Reduction Test. In fact, by substituting hydrochloric acid for the Ewald meal, we eliminate both (a) and (b) above.

The figures shown demonstrate these faulty mechanisms. Thus there is a retardation of acid reduction in cases of pyloric obstruction or spasm (Figs. 6 and 7) and in cases of insufficient production of pancreatic alkali, whether brought about experimentally (Fig. 1) or by disease of the pancreas (Fig. 4). Norris and I (7) also showed a retarded rate of reduction in chronic nephritis and in diabetes, two diseases commonly associated with a diminished blood alkali reserve, which in turn brings about a diminished secretion of pancreatic alkali. In all of these cases there is delayed emptying. Even in cases of rapidly emptying hypertonic stomachs, in which flux dominates over reflux, I have found that the acid remains high.

Conversely, when reflux or regurgitation is facilitated, as by gastro-enterostomy (Fig. 5) or where there is an abundant secretion of alkali (Apperly and Crabtree (6)), the stomach empties rapidly with a sharp fall in the acid curve (shown in some cases in Fig. 3).

I have found no definite deviation from the normal in patients with gall bladder disease or with achylia gastrica.

Some other physiological factors governing this test have been discussed elsewhere (Apperly and Cary (5)).

CONCLUSION

From experimental and clinical evidence it is concluded that the Acidity Reduction Test is superior to the gruel or Ewald fractional test-meal.

The Relation Between the Acid-Base Equilibrium and the Gastric Bacterial Flora*

By

MARION HOOD, Ph.D.

and

LLOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

BACTERIA are continuously being introduced into the body, from the air, from food, and in countless ways in which the lips come in contact with non-sterile surfaces. For the most part these organisms are non-pathogenic and apparently exert little or no influence on the body. Under certain conditions, however, pathogenic organisms are the contaminants, and disease may or may not result, depending upon the ability of these organisms to become established in the body. Such power is due not only to the virulence or adaptability of the exogenous flora, but also to the break down in the various mechanisms by which the body is able to protect itself. This present work is a study of one of the protective mechanisms by which the body defends itself against this entrance.

All of the experiments were performed on patients in the medical wards of the Research and Educational Hospital of the University of Illinois, College of Medicine. Although none of these persons could be considered entirely normal from a health standpoint, those exhibiting any particular dysfunction of the gastro-intestinal tract or suffering from primary anemias were not used. Patients showing relatively low gastric acidity were chosen for many of the experiments. This was necessary in as much as this work was concerned with bacterial growths which usually are associated with this type of gastric contents. No doubt such cases were more frequent in this hospital population than would be in a normal cross section of healthy adults. Several series of experiments reported by Davies and James (1930), Vanzant, Alvarez, et al (1932) and Bloomfield and Keefer (1928) showed that there is a consistently higher percentage of true as well as apparent cases of achlorhydria in individuals with advancing years. The latter group of workers showed that this anacidity was proportional to the lowering of physical fitness although the conditions were apparently unrelated to disease of the gastro-intestinal tract.

A series of six experiments were carried out to show the relation of the hydrogen-ion concentration to the bacterial growth of the stomach.

Experiment I: The Relation of Hydrogen-Ion Concentration to Bacterial Growth.

In this experiment aspirations by means of Rehfuss tubes were made from the fasting stomachs of a group of 106 patients. The hydrogen-ion concentration was determined by a colorimetric method and bacterial growth by plating out one standard loop of material on the surface of plain agar. Although there were a few marked discrepancies the following table shows the general relation between hydrogen-ion concentration and bacterial growth in human gastric contents. Graph I shows the actual values.

Less than pH 1.0	Sterile.
Between pH 1.0 and 2.0	Occasional colony.
pH 3.0	Borderline of bacterial growth.
Above pH 3.0	Heavy bacterial growth.

This corresponds in general to the results reported by Bartle and Harkins (1925) and Gregerson (1916).

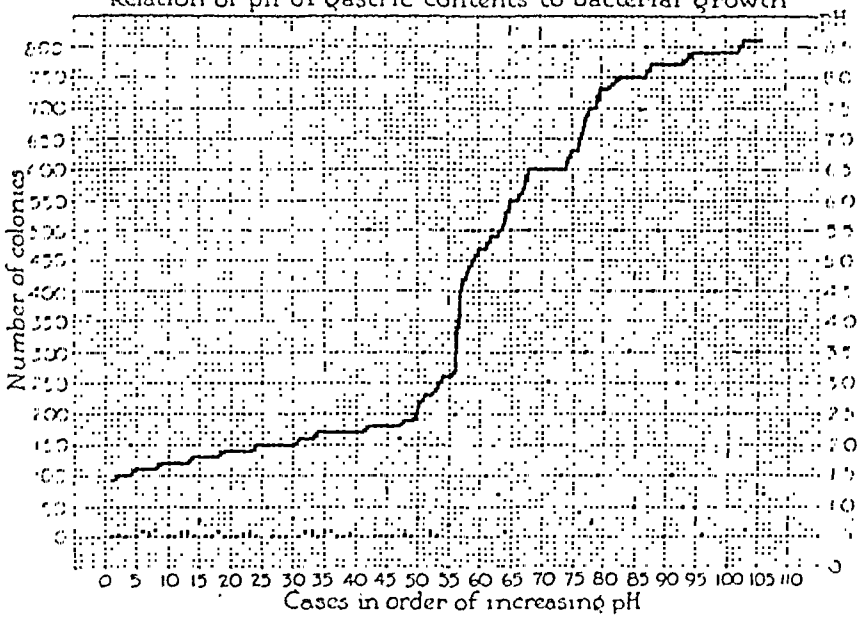
Experiment II: Changes in Hydrogen-Ion Concentration and Bacterial Flora of the Stomach During a Period of Three and One-Half Hours.

The Rehfuss tube was inserted and control aspirations were obtained from the fasting stomach of five patients. Each subject was permitted to eat breakfast with the tube in place. Aspirations were then made at fifteen minute intervals for two and one-half to three and one-half hours. Cultures and hydrogen-ion determinations were taken on each sample to show the relationship between the acid-base equilibrium and viable bacterial flora over a period of several hours. The increased concentration of hydrogen-ions within the gastric contents was associated with a decrease in the viable bacterial flora following in general the relationship noted in Experiment I. Graph II demonstrates this fact. Similar results are reported by Johnson and Arnold (1932) and Nedzel and Arnold (1932).

Experiment III: The Influence on the Hydrogen-Ion Concentration and the Viable Bacterial Flora Produced by the Introduction of Acid or Alkali into the Stomach.

The Rehfuss tube was inserted and a control aspiration was obtained from the fasting stomach of each of nine patients. This material was cultured and the hydrogen-ion concentration determined. If the reaction was more alkaline than pH 3.5, 50 c.c. of 1 per cent hydrochloric acid were added; if more acid than pH 3.5, 50 c.c. of phosphate buffered alkali were added. After five minutes a second aspiration was made and treated as the first fraction. With the shifting of the pH of the stomach contents because of the addition of the acid or alkali there appeared a corresponding change in the abundance of growth of the gastric flora. In this series of nine cases and in others reported elsewhere, the response to the acid was much more readily obtained than was a similar response to the alkali. (See Graph III).

Experiment IV: The Influence on the Hydrogen-Ion Concentration and the Viable Bacterial Flora Produced by the Introduction of Organic Acids into the Stomach.



Various organic acids were substituted for the mineral acid of Experiment III to find whether or not these would exert a similar influence upon the hydrogen-ion concen-

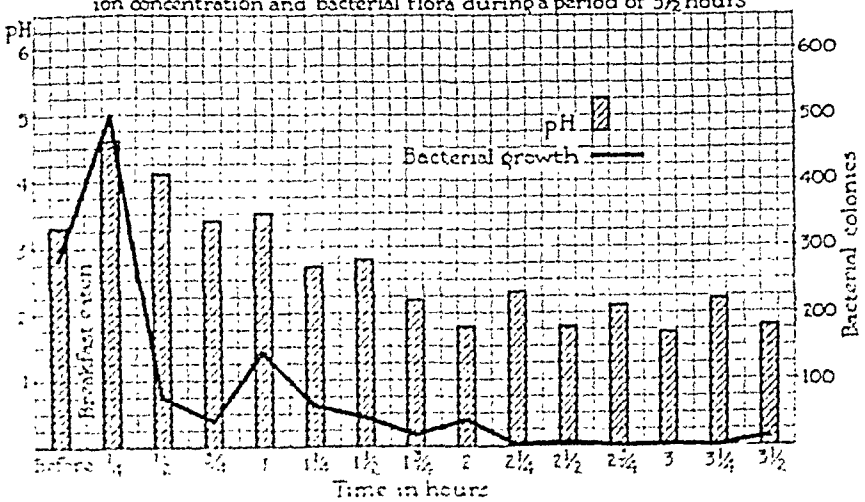
Submitted October 21, 1936.

Graph I

Relation of pH of gastric contents to bacterial growth

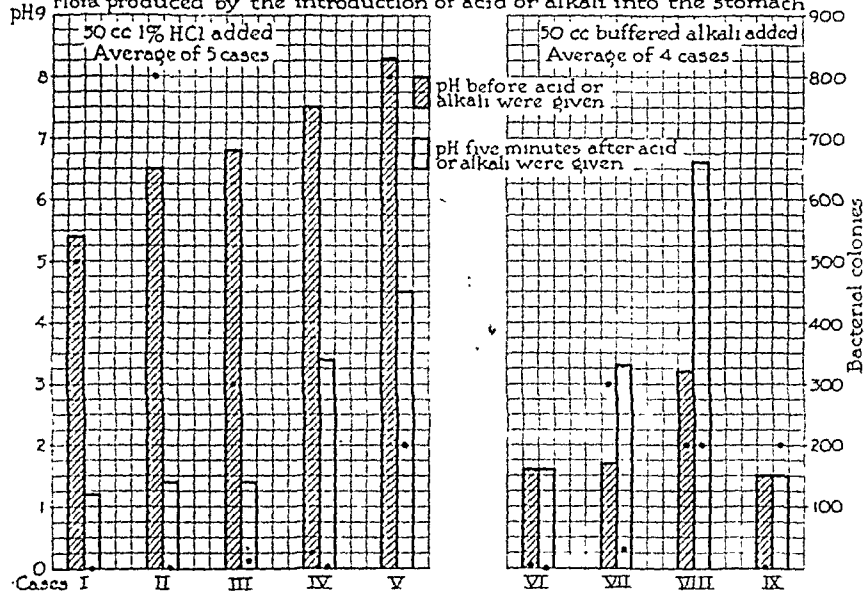
tration and viable bacterial flora of the stomach. A Rehfuss tube was inserted into the fasting stomach of each of three patients and control aspirations were made. Fifty cubic centimeters of 1 per cent hydrochloric acid were introduced and five minutes later were aspirated. On four succeeding days the above experiment was repeated, substituting similar amounts of various organic acids for the mineral one first used. Cultures and hydrogen-ion determinations were made on each specimen and the results are shown on Graph IV.



In this series of cases the lemon juice appeared to be as efficient in acidifying gastric contents and thereby rendering many of the organisms non-viable as an equal amount of 1 per cent hydrochloric acid. In an *in vitro* experiment Knott (1923) found the organic acids very deficient in germicidal power. Kugelmass (1935) reported a series of cases where fruit juices were given to children. He found that fruit juices fluctuating about pH 3.0 stimulated, within the first fifteen minutes after ingestion, a gastric pH of about 3.5. The titration curves showed that the juices are mixtures of weak acids and their salts, containing small amounts of free acids. The presence of free acid was shown by Clark (1915) to be the determining factor of bactericidal power.

Experiment V: The Length of Time the Fasting Stomach Retains Acquired Acidity.

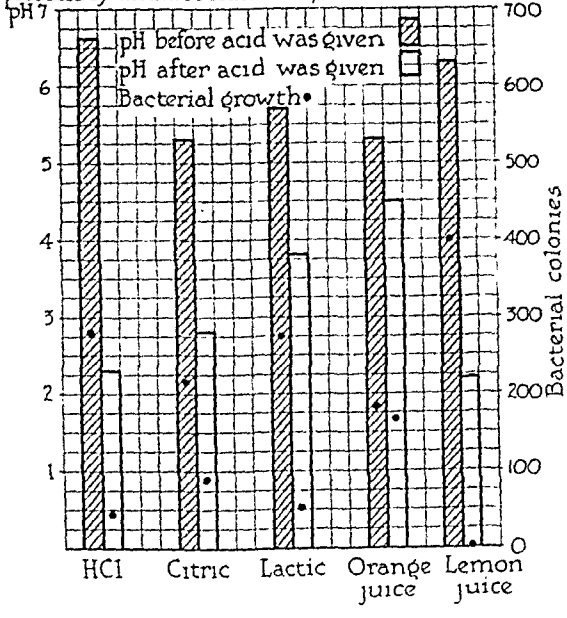
Experiments III and IV show that the addition of acid, either mineral or organic, affects the acid-base balance of the stomach with a comparable change in the number of microorganisms which can be cultured from the contents.



Graph II

Average taken from five cases showing changes in hydrogen ion concentration and bacterial flora during a period of 3½ hours

Graph III

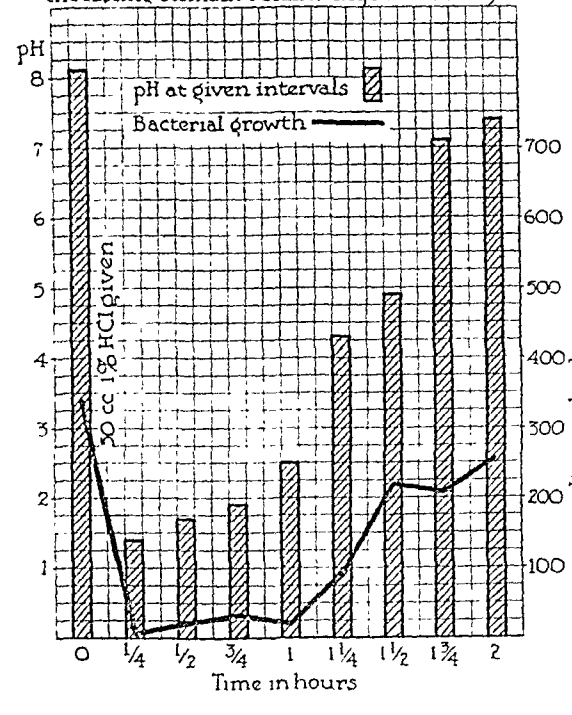


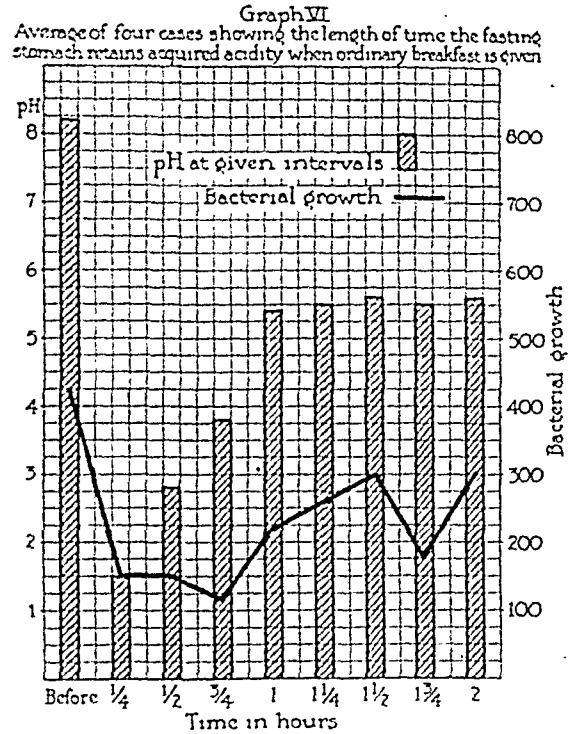
The influence on the hydrogen ion concentration and the viable bacterial flora produced by the introduction of acid or alkali into the stomach

In a series of five cases aspirations were made by means of Rehfuss tubes inserted into the fasting stomachs. Cultures and hydrogen-ion determinations were taken on these and all subsequent fractions. Fifty cubic centimeters of dilute hydrochloric acid of pH 1.2 were then introduced through the tubes. Aspirations were made at fifteen minute intervals until the reaction approached or equaled the original pH value. This is shown on Graph V. The stomachs of these five patients retained the acquired acidity for approximately one and one-half hours or sufficiently long to aid the action of the peptic enzyme and to give protection against bacteria which may be introduced during the digestive period. Boldyreff (1914), using one man and four dogs reported a return to normal acidity in from forty-five to sixty minutes.

Graph IV

Average of three cases showing the influence on the hydrogen ion concentration and the viable bacterial flora produced by the introduction of organic acid into the stomach





Experiment VI: The Length of Time the Stomach Retains Acquired Acidity After a Normal Breakfast is Ingested.

To be of physiological importance this change in reaction must be effective when food is taken into the stomach.

Graph V

Average of five cases showing the length of time the fasting stomach retains acquired acidity

Two patients, showing anacidity in the control aspirations, were chosen for a series of tests to show whether or not the addition of food shortened the period of activity of the introduced acid. Under fasting conditions Case I showed retention of acquired acidity for a period of more than two hours. With the addition of a normal breakfast this time was approximately one hour. The addition of food in Case II reduced the period of acid retention from one and one-half hours to three-quarters of an hour. The results are shown in Graph V. The explanation lies in the fact that part of the acid combines with the food leaving a smaller amount of free or effective acid present. Much the same conclusion was drawn by Cornwall and Le Frenais (1921) who found the total acid greater after a test meal because the food stimulated the gastric glands to greater secretory activity. The free acid was decreased in amount because much of it went into combination with the ingested food.

DISCUSSION

Bacterial growth in general parallels the acidity of the gastric contents. This was shown by cultures of gastric material taken from 106 cases reported in Experiment I. The borderline for growth was about pH 3.0. Cultures of gastric contents showing acidity above this value were, for the most part, sterile and those of lesser acidity produced abundant growth. Thus the hydrogen-ion concentration of the normal stomach which varies around pH 2.0 has the power of rendering viable bacteria non-viable and therefore aids in protecting the body from intragastric contact with living bacteria. It was shown by following the course of digestion for a three and one-half hour period, that the acidity of the normal stomach is not a brief phase in the digestive cycle to be followed by low acidity with consequent lack of protection, but that it maintains itself throughout the intradigestive phase. Fasting stomachs that have relatively low acidity but normal secretory power produce sufficient acid during digestion to retain the protective power over a period equal to the normal time between meals.

Experiment III showed that it is a relatively easy matter to change the reaction of gastric contents from that of neutrality or alkalinity to acidity by the addition of comparatively small amounts of dilute hydrochloric acid (50 c.c. of 1 per cent hydrochloric acid). This is significant for the large group of apparently normal people who have hypo-or anacidity and thus have a densely populated bacterial flora in the lumen of the stomach. The acquired acidity was retained by the fasting stomach for approximately one and one-half hours. When a normal breakfast was eaten following the administration of the acid, the change in pH was retained for a shorter period of approximately three-quarters of an hour. During this period of artifically produced acid gastric contents the patient maintains a normal gastric flora.

This protective action may be brought about by substituting 50 c.c. of 1 per cent organic acids for the dilute hydrochloric acid if the resulting hydrogen-ion concentration is below pH 3.0. The juice of one-half lemon in 50 c.c. of water proved to be the most effective acid used although the initial pH was not more acid than that of the citric or lactic acids employed. Thus the old idea of giving lemon juice in cases of gastro-intestinal disturbances when anacidity was suspected is substantiated.

To render a naturally acid stomach alkaline is a much more difficult procedure. The addition of the alkali apparently excites the glands to greater activity so the resulting reaction is the same or only slightly more alkaline.

CONCLUSIONS

1. Cultures of the contents of fasting stomachs showed a bacterial growth that paralleled the hydrogen-ion concentration of this material in approximately the following manner:

Less than pH 1.0	Sterile.
Between pH 1.0 and 2.0	Occasional colony.
pH 3.0	Borderline of bacterial growth.
Above pH 3.0	Heavy Bacterial growth.

2. Continuing the observations over a three and one-half hour period showed a variation in hydrogen-ion concentration. This was associated with a parallel change in the viable bacterial flora.

3. The alterations in the hydrogen-ion concentration of the gastric contents produced by the ingestion of dilute mineral or organic acids were associated with a decrease in the viable bacteria flora. The ingestion of buffered alkaline solutions were associated with an increase in the viable gastric flora.

4. The addition of 50 c.c. of 1 per cent hydrochloric acid to the fasting stomach shows a retention of free acid for approximately one and one-half hours. This period was reduced to somewhat less than one hour if food was ingested.

Colloidal Aluminum Hydroxide in the Treatment of Peptic Ulcer*

By

CLEMENT R. JONES, Jr., M.D.†
NEW ORLEANS, LOUISIANA

THE purpose of this paper is to report briefly the results obtained in the treatment of patients affected with X-ray positive peptic ulcer.

The patients were selected in the following manner: First, they had the complaints which lead one to suspect the presence of a peptic ulcer, and second, no matter how suggestive these complaints, their histories and physical findings may have been, they were not, with the exception of Case 19, admitted to this group unless there was positive X-ray evidence of peptic ulcer. It is safe to assume, then, that they are all *bona fide* cases of peptic ulcer of one type or another.

The majority of these patients was from the white male outpatient or ward medical service at the Charity Hospital. Economically, for the most part, the subjects were from the lowest level, though some living in the country have the good fortune to be able to obtain a wide variety of dairy and other farm products suitable for use in a soft diet. The Creole cooking, which is the normal diet of these patients, while it is delectable beyond words to the normal individual, is about as far removed from what a person suffering from peptic ulcer should eat as any diet one can imagine. A soft diet for our patients means much more of a change of dietary habit than does a soft diet for a Northern patient, whose normal diet is relatively bland and free from strong seasoning substances.

In considering the possibility of giving these patients any appreciable amount of rest, it was at once seen to be impossible, for those who had any sort of job did not dare let it go, and those who were not employed could not be given bed rest in the Hospital due to crowded conditions incident to the demolition and reconstruction of a large portion of the institution. The few patients who were admitted directly to the wards were regarded as ambulatory and were allowed to be up and around during the day and were given improvised beds of blankets on the floor at night. Home conditions were such that no more than the most meager limitation of activity could be obtained. As examples of the degree to which activity could be limited let me cite two cases: A man who was accustomed to operate a pneumatic riveter had his job changed to operating an acetylene torch; another who did the heavy pulling necessary in recovering a large fishing net was able to change to some of the less arduous duties of a commercial fisherman. I think from these instances it is clear that the ordinary benefits obtained by a "rest cure" were negligible. The predominating nationalities of the patients are French and Spanish. The high strung temperament and often emotional instability which is inherent in people of such descent may predispose to ulcer and is an added difficulty in an attempt to obtain improvement after the ulcer is present.

The methods of treatment of peptic ulcer are almost without number, and of every method there are countless modifications. Diet regulation, rest and neutralization of acidity stand out as important factors in almost all instances. The multiplicity of treatments is not necessarily to be deplored for though it indicates the lack of a specific, one type or form of treatment may aid in the attainment of remission in a given case that has been or would be unaided by any of several other methods or modifications thereof. It is not my purpose to add a method to the many now in existence, but merely to record some rather favorable results in a group of peptic ulcer patients treated with aluminum hydroxide.

B. B. Crohn (1), in 1929, was the first to report on the use of aluminum hydroxide in this country. Einsel and Rowland (2) reported, in 1932, on the use of aluminum hydroxide, both in the colloidal form and in a non-colloidal form, but since the latter form had no appreciable acid-combining power, they abandoned it for the colloidal preparation which seemed to have a very good acid-combining power. Einsel, Adams and Myers (3) reported 110 patients with peptic ulcer treated with colloidal aluminum hydroxide, with but 8 per cent failures. The treatment consisted of six feedings per day followed in 30 to 60 minutes by 4 to 12 c.c. of a gelatinous preparation of colloidal aluminum hydroxide. Woldman and Rowland (4, 5) reported on the use of a continuous intragastric drip for the administration of a diluted colloidal aluminum hydroxide. The results obtained by this method and checked by X-ray were extremely favorable. With this method, I have had only slight experience (Case 19). Adams, Einsel and Myers (6) conclude in part that, due to the

Submitted December 25, 1936.

administration of colloidal aluminum hydroxide, there is a decrease of total amount of acid secreted by the stomach and that this total tends to become progressively lower with continued use of the drug. That this reduction of acid secretion is not due to permanent damage to secreting cells is indicated by the fact that even after several months of treatment, histamine injections give the same acid response that was obtained previous to treatment. After many months of continuous administration of aluminum hydroxide there is no significant change in serum calcium, total base or carbon dioxide content of the blood.

It seems that the following facts are established. Aluminum is not absorbed from the intestinal tract to any significant extent. Aluminum hydroxide taken by mouth has no effect on the acid-base equilibrium of the blood. The preparation of colloidal aluminum hydroxide used in these cases has an acid-combining power of 15 to 16 volumes of tenth normal hydrochloric acid. The dosage used varied from 4 c.c. three times a day to 8 c.c. four times a day, taken after meals and at bedtime. An ordinary soft diet was given in conjunction with the drug. A few cases were given 0.3 gm. sodium bromide and 2 c.c. tincture hyoscyamus three times a day and a few were given mineral oil as their bowel habits required. No two hour or hourly feedings, no alkalies and no injections of any kind were used in any of this series of cases.

AUTHOR'S STUDY

In this group there are 22 males and two females, the average age being 42 years, ranging from 12 to 64, with about equal distribution in the third, fourth, fifth, sixth and seventh decades. In ten cases the symptoms had been present less than one year, averaging six months. In 12 cases the symptoms had been present over a year, averaging seven years. The most common complaint was epigastric pain definitely related to meals. Well localized epigastric tenderness was present in almost all cases.

G = Gastric
D = Duodenal
AP = Accessory pocket

Immediate results were as satisfactory in the chronic cases as in the acute ones except that the only case in which the radiologic evidence of healing was not entirely satisfactory after a reasonable length of time (60 days) was a man who had had the disease for 20 years.

The following cases have been selected because they illustrate the various types of cases seen in this group. Case 1 is presented largely because of his age.

Case 1. W. S., a white male, aged 12, was seen April, 1936, complaining of post-prandial pain of four months' duration, relieved by sodium bicarbonate, or vomiting. He

had, however, been subject to gastro-intestinal upsets all of his life according to the statement of his mother. Fluoroscopic examination on April 27, 1936, showed an ulcer of the fundus one centimeter in diameter. His treatment was started at once, but the ordinary powders and diet failed to relieve him more than temporarily. On May 15, 1936, obtaining some colloidal aluminum hydroxide, he was given 12 c.c. three times a day, diet consisting of strained vegetables, milk products, soft boiled eggs and toast. Symptomatic improvement was noted almost at once, and he continued to improve until symptom-free on June 26, at which time there was no evidence of gastric or duodenal disease on X-ray examination. He is a well and healthy boy at the present time, gaining weight and free of gastric complaints for the first time in his life.

Case 2 is selected as being approximately the average patient except that the gastric ulcers were outnumbered by the duodenal ulcers.

Case 2. D. R., aged 46, was re-admitted to the hospital on August 11, 1936, complaining of epigastric pain of two and a half years' duration, three or four hours after the noonday meal. The pain was followed by nausea and vomiting which gave relief. He had been a patient in the same ward in March, 1936, at which time his X-ray showed an ulcer 4 by 7 mm. on the lesser gastric curvature. This finding was also present on August 13. Epigastric tenderness was present, and his gastric analysis showed 45° free and 82° total acid. He had a slight secondary anemia. Starting on August 20, he was given colloidal aluminum hydroxide, 4 c.c. three times a day along with a soft diet. After two days he had no further pain or discomfort. On September 10, or 21 days after treatment was initiated, he had a normal fluoroscopic examination. He remains well to the present time and has practically discontinued the medication.

Case 4 is presented because of the extremely rapid loss of X-ray evidence of ulcer which is not unusual in this method of treatment but for one case is naturally open to some question.

Case 4. C. M., aged 52, was admitted to the hospital on September 5, 1936, complaining of pain in the epigastrium following meals, which had occurred after every meal for the last three months and for the two months previous had occurred with increasing frequency. On September 10, a duodenal cap ulcer with crater formation was demonstrated by fluoroscopic examination. Gastric contents showed free hydrochloric acid 63°, total 72°. On September 12, aluminum hydroxide therapy was instituted along with a soft diet. He was relieved of pain at once, and on September 19, or seven days after treatment was started, he had a fluoroscopic examination that showed no abnormality of stomach or cap. Six months later he had gained weight and was feeling in perfect health.

Case 11 is presented to illustrate the healing of a gastric ulcer with an accessory pocket.

Case 11. A. G., aged 52, a fisherman by trade, was admitted to the hospital in September, and on September 24, showed an accessory pocket of a perforating ulcer above the incisura angularis with 50 per cent six hour retention. On September 26, aluminum hydroxide, 4 c.c. every third hour, was started together with a bland diet. After two weeks the aluminum hydroxide dosage was reduced to 4 c.c. three times a day. He felt well in four days and insisted on going out to the fishing grounds. The fluoroscopic examination on October 5 showed the pocket unchanged in size but not tender and on November 13, the fluoroscopic examination showed the pocket almost gone and not tender.

Case 19 is presented since it is the only severe hemorrhage case in the group and demonstrates the use of the continuous intragastric drip method of administration of colloidal aluminum hydroxide.

Case 19. C. V., a 33 year old mechanic, was admitted to the hospital on October 21, 1936. For five weeks he had had an epigastric pain which was relieved by food. Five days previous to admission he had started to become weak and pale and shortly began to pass tar-colored stools. He rapidly became so weak that he was unable to stand up and was brought to the hospital in a most depleted state. Shortly after admission there was expelled a large amount of coffee-ground vomitus. The upper portion of his abdomen was generally tender but not rigid. He was treated for shock and given a transfusion of 450 c.c. of citrated blood on the day of admission and 250 c.c. four days later. Aluminum hydroxide was started, 4 c.c. every third hour, on October 23. He received about eight such doses in the first 24 hours of aluminum hydroxide treatment and was then given the medication by a continuous intragastric drip* which was continued day and night for seven days. In this time he received between 250 and 275 c.c. daily of colloidal aluminum hydroxide diluted so as to make about a 25 per cent solution. Several aspirations through the nasal tube showed from zero to 5° of free hydrochloric, but after the first day no blood was detected. He became rather constipated but as he was getting very little food by mouth no effort was made to cause a bowel movement. After five days of the continuous drip he had a movement consisting largely of the tar colored material following which his stools remained negative for occult blood. He was up and around in 12 days after admission. The red count was 1,775,000 on the day of admission and 19 days later on discharge to the out-patient department, it was 3,505,000. On November 30, his red cell count was 5,325,000. His fluoroscopic examination the day before discharge failed to reveal an ulcer. Did the ulcer heal in that time, or was it in a position not amenable to demonstration? I do not know. Did he have an ulcer to start with? I believe he did.

SUMMARY

1. A brief abstract of the case histories selected from 24 patients affected with peptic ulcer, all of whom were treated with colloidal aluminum hydroxide, is presented.

2. All but one of the 24 patients have had complete relief of symptoms. The one exception is the patient, presented as Case 14 in the chart, who has been sick for 20 years and had only slight X-ray improvement in 60 days. Three showed a gradual relief of symptoms so that it is difficult to say in how many days they became symptom-free. The remaining 20 showed a prompt relief that could be accurately measured in days, their average time for relief of pain being 3.0 days. Only three required longer than four days. Lessening of pain always started at once upon the institution of treatment.

3. Of the 16 patients who have been re-rayed, 13 (nine duodenal and 4 gastric) showed disappearance of their ulcer in an average of 30 days. One duodenal ulcer was not improved in 12 days, while another duodenal ulcer showed improvement in 60 days. One gastric ulcer with accessory pocket formation showed improvement in 11 days and almost complete disappearance of the pocket in 49 days.

*Using an especially constructed apparatus lent by the Cleveland Chemical Associates who also furnished the colloidal aluminum hydroxide.

A Review of Intragastric Photography

By

BENJAMIN M. BERNSTEIN, M.D.
BROOKLYN, NEW YORK

IN April, 1930, Bernstein and Gray (1) described their experience with intragastric photography in twenty patients. Since then, the senior author has continued his interest in the subject and has had opportunity of observing a large number of patients, many of whom were followed up by surgery or autopsy. Since our first report, a number of articles and monographs in English, German and French have been published. It would seem of advantage to review at this time the present state of our knowledge and experience with intragastric photography.

The *instrument* used in carrying out this procedure, referred to as the "gastrophotor," has undergone considerable change in its mechanism and the photographic results obtained since its invention by Back and Heilperin of Vienna about seven years ago. Progress has been made in the refinement of technique as well as in the study of the criteria for diagnosis. Briefly described, the apparatus consists of a long tube-like affair, no thicker than the familiar Ewald stomach tube, with a double camera and a light at its end. The electric current is carried and inflation is done through the handle. There is likewise, here, an arrangement for shutter displacement. In the bulb at the tip, a bluish light of great intensity, producing no heat, is flashed on momentarily after the camera "eyes" have opened. The complete circumference of the stomach and about two-thirds of its area is seen in the sixteen pictures obtained. The location of the apparatus in the stomach is observed by fluoroscopy. Its orientation to the respective walls and curvatures is determined by cutting and loading the films in a distinguishing manner. The necessary photographic distance is obtained by moderate gastric inflation. After the films have been developed, they are enlarged, printed and studied for diagnosis.

The great value of photographically studying the gastric mucosa can scarcely be doubted, particularly after one has obtained a fleeting glimpse of it by means of a gastroscope. How much more satisfactory to be able to study the permanent record of such a view, usually obtained with such difficulty! Aschner and Berck (2) believed the method to be a valuable adjunct to diagnosis. Finkelstein (3) in 1931 and more recently again discussed his results in a large number of cases. Thal (4) and later Cunha (5) contributed to the general knowledge of the procedure and its diagnostic value. Rehfuss (6) has commented favorably; also Whigham (7) and Wyard (8) in the British literature. Rehfuss presented an exhibit of his personal experience with this procedure at the Scientific Assembly of the American Medical Association in 1935. A chapter of L. W. Kohn's "Diseases of the Digestive System." (9) has been devoted to the subject. In the French and German literature, Becart (10), Ehrenteil (11), Garin and Bernay (12), Heilperin and Porges (13) Haudek (14), Pauchet (15), and others have also contributed to our knowledge.

In the study and use of this method of intragastric

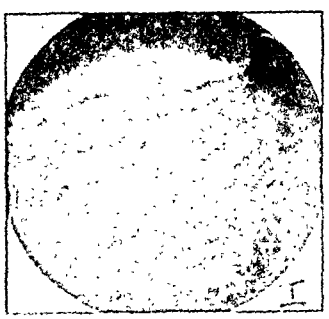

Fig. 1 is that of a normal mucous membrane. The numerous small white spots seen in many pictures are reflections from fluids sticking to the mucous membrane.

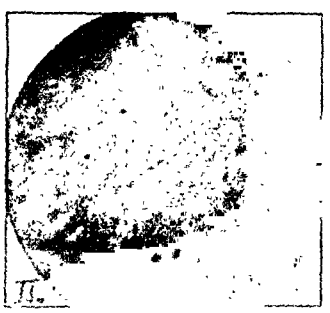

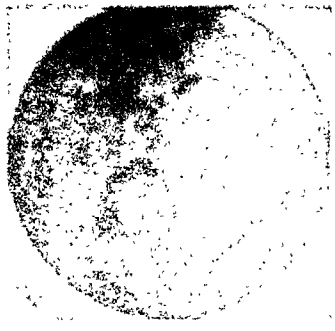

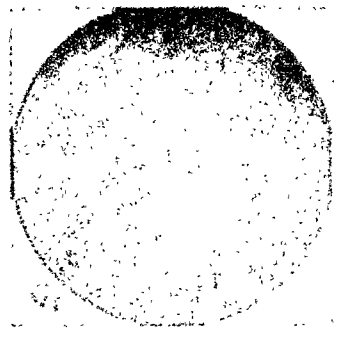

Fig. 2 is that of an ulcer-characteristic crater-like formation and raised edge.

Fig. 3 is that of a carcinoma and one readily notices the sharp demarkation and change from the normal surrounding mucosa—also the elevations and loss in normal structure.

Alcohol as a Stomachic*

By

LUISE KRUEGER, M.D.

and

F. C. MacINTOSH, M.A.

MONTREAL, CANADA

THAT alcoholic beverages in small doses may promote gastric digestion has been known from time immemorial. The secretagogue action of alcohol on the gastric glands was discovered in the middle of the 19th century (Frerichs (3), Cl. Bernard (2)). Our present knowledge of the effect of alcohol on gastric digestion may be summarized briefly as follows (*cf.* Babkin (1)). Alcohol in dilute solution (5 to 20 per cent), introduced into any part of the digestive tract, quickly evokes a copious flow of gastric juice, which has a high acidity and a very low digestive power. When alcohol in strong concentrations is applied directly to the gastric mucosa, a profuse secretion of mucous alkaline fluid occurs; the secretion of normal gastric juice is inhibited in such cases, the inhibition lasting for several days. The fact that a weak alcoholic solution stimulates gastric secretion suggested its clinical use as a test-meal (*cf.* Katsch (4)). The alcohol test-meal was often employed, especially in Germany (under the name of *Alkoholprobetrunk*), before the secretagogue effect of histamine was discovered. *In vitro*, alcohol in 1 to 2 per cent concentration has no significant effect on the peptic activity of the gastric juice (Zitovich (7)); when weak alcoholic drinks are taken in conjunction with a meal, the concentration of alcohol in the stomach is probably not greater than this.

The effect on gastric secretion of adding alcohol to a meal was systematically studied in Pavlov's laboratory by Zitovich (7), who used dogs equipped with pouches of the stomach. He found that, when 5 or 10 per cent alcohol was added to a meal of meat, bread or milk, the volume of gastric juice secreted in response to the meal was greatly increased. Alcohol in the same concentration also counteracted the inhibitory effect of fat on the gastric secretion. The secretagogue action of alcohol was especially striking when the first or reflex phase of the secretion was eliminated by introducing the test-meal (in this case, meat) directly into the stomach through a gastric fistula. As Fig. 1 shows, the addition of alcohol restored the course of the secretion to normal and shortened the emptying time of the stomach by one hour. The peptic power of the juice secreted during the first two hours was, however, lower (average, 41 Mett units) than when meat was given with water by mouth (average, 177 Mett units). Zitovich's experiments thus show that, when through loss of appetite the gastric glands fail to give their normal prompt response to the taking of a meal, the ingestion of a beverage of low alcoholic content will help to restore the proper digestion of the food. Nevertheless, the secretion activated by alcohol was not, in these experiments, a perfect substitute for normal reflex secretion, since the enzyme content of the juice was comparatively low.

In the present series of experiments we have been able to show that alcohol, besides stimulating the secretion of fluid and acid by the stomach, may, in certain circumstances, stimulate also the secretion of pepsin. The necessary condition for this additional action is that the alcohol should be relished. It then becomes a positive conditioned stimulus for gastric secretion, increasing the output of pepsin reflexly through activation of the vagal secretory centres.

METHODS

In these experiments we used a dog equipped with a Pavlov pouch of the stomach and a gastric fistula. The experiments were done in the morning, the usual precautions being taken to prevent psychical stimulation of the secretion. 200 c.c. of 5 per cent ethyl alcohol of good quality, warmed to 37° C., was introduced slowly into the stomach through the gastric fistula while the gastric glands were at rest, and the resultant pouch secretion was collected. In control experiments, two other dogs were used, one with a Heidenhain pouch (vagal innervation destroyed) and one with a Bickel pouch (completely denervated) and a gastric fistula. The Bickel-pouch dog could be similarly given alcohol by the gastric fistula; the Heidenhain-pouch dog could be given alcohol by rectum. None of the dogs had ever received alcohol before. The determinations made on the pouch juice were: free and total acidity by titration to Töpfer's reagent and phenolphthalein respectively, and pepsin by Nirenstein and Schiff's (5) modification of Mett's method.

*From the Department of Physiology, McGill University.
Submitted January 14, 1937

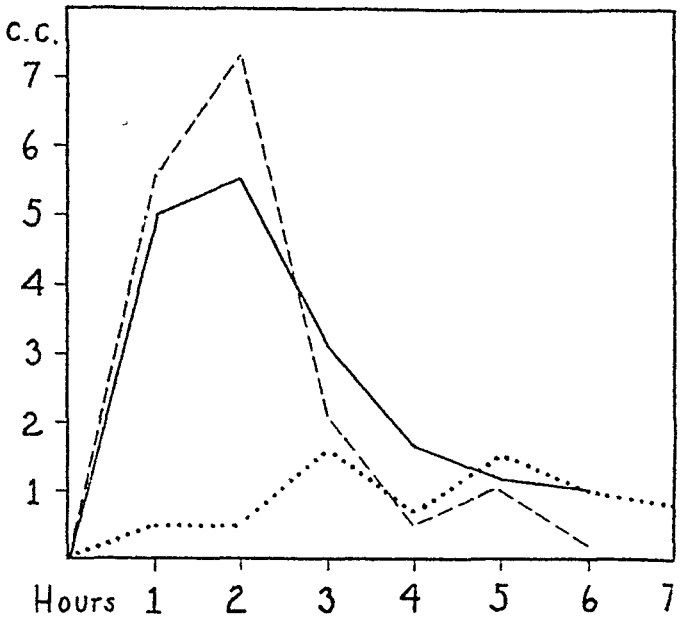

Fig. 1. Volume of juice (Pavlov pouch) secreted in response to the following meals: 100 gm. meat + 100 c.c. water by mouth ——; 100 gm. meat + 100 c.c. water by gastric fistula . ; 100 gm. meat + 100 c.c. 5 per cent alcohol by gastric fistula — —.

RESULTS

The results of the first series of experiments with the Pavlov-pouch dog were uniform. Soon after the dilute alcohol was injected the animal's breath smelled of alcohol and it began to lick its lips. Within 2 or 3 minutes gastric juice began to flow from the pouch. The secretion was brisk for about an hour, and stopped after about 2 hours, when the main stomach was found to be empty. A typical protocol from this series is presented.

Experiment Feb. 4, 1936. Pavlov-pouch dog, female, 14 Kg.

9:05 a.m.	Animal placed on stand. Stomach empty.			
9:05- 9:20	Pouch secretion 0.15 c.c. mucous fluid.			
9:18- 9:20	200 c.c. 5% ethyl alcohol introduced through gastric fistula.			
	Vol. c.c.	Free acidity m.eq./L.	Total acidity m.eq./L.	Pepsin Mett units
9:20- 9:50	3.90	111	120	60
9:50-10:20	2.90	129	138	73
10:20-10:50	0.95	100	109	97
10:50-11:20	0.30			
	8.05 c.c.			

The same experiment was repeated many times on this dog between the end of January and the middle of December, 1936. The course of the "alcohol" secretion, and its total volume and acidity, were always about the same. The volume varied between 7.3 and 9.8 c.c., though latterly it was generally near the upper limits. The concentration of pepsin in the juice, however, underwent a striking change. After the first month or two, during which the experiments were repeated about twice a week, the values for pepsin became gradually higher and higher with each successive injection of alcohol. These results are illustrated graphically in Figure 2. The upper graph shows the volume of juice secreted in eight experiments, selected as typical of different stages during the investigation. The lower graph shows the concentration of pepsin in the juice secreted in these same experiments.

The average value for pepsin concentration increased from 33 Mett units in January to 462 in September—*i.e.*, there was an increase in the digestive power of 1400 per cent. Thus alcohol, which at first did not stimulate the output of pepsin, came in this animal to be a very strong stimulus for the peptic cells.

The other two dogs, whose pouches had no vagal innervation, gave very uniform low values for pepsin (average, less than 50 Mett units) during this whole experimental period.

It was suspected that the explanation of the changed reaction of the Pavlov pouch was that alcohol had become in this animal a positive conditioned stimulus for gastric secretion. There were several reasons for supposing this. During the action of alcohol the dog was clearly slightly intoxicated, and appeared to be in particularly good humor. Although the alcohol was introduced directly into the stomach and the animal was not allowed to smell or taste it, it was soon excreted by the lungs, and the dog could be seen to lick its lips at intervals during the experiment. After the experiments had gone on for some time, it would wag its tail violently, show the greatest pleasure when preparations for the experiment were being made, and follow the movements of the experimenter with much interest. Once or twice a small amount of gastric juice was secreted even before the alcohol was introduced into the stomach. On several occasions the dog was offered 5 per cent alcohol to drink, and took considerable quantities freely. The drinking was followed by a fair secretion of gastric juice of high peptic power. Thus in one of these experiments (Experiment of Oct. 12), when the dog took 175 c.c. of 5 per cent alcohol, the total volume of secretion for two hours was 7.1 c.c. and the average peptic power 271 Mett units. The acidity of the juice was as usual high.

It, therefore, seemed reasonable to conclude that the dog had learned to like alcohol, or perhaps rather the effects of alcohol, and that alcohol had thus become a positive conditioned stimulus for the secretion of pepsin. The actual stimulus would probably be the taste of the alcohol as it was excreted in the breath.

This conclusion is strongly supported by the following experiment, in which the alcohol was given by rectum, instead of through the gastric fistula as usual. The animal had never before received a rectal injection, and objected violently. The digestive power of the juice secreted in response to the alcohol was low, and remained low after a second portion of alcohol had been given through the gastric fistula in the usual way, although the volume of the secretion was nearly normal. In previous and subsequent experiments, in which the alcohol was introduced directly into the stomach under more pleasant circumstances, the diges-

tive power of the juice secreted was very high. The protocol of the above experiment is given below.

Experiment Oct. 14, 1936. Pavlov-pouch dog, female, 14 Kg.

		Vol. c.c.	Total acidity m.eq./L.	Pepsin Mett units
10:00 a.m.	Dog placed on stand.			
10:00-10:30	Pouch secretion 0.5 c.c.			
10:30	Small water enema given to wash out bowel. Dog very excited, struggled, tried to bite.			
10:30-10:50	No secretion.			
10:45-10:50	200 c.c. 5% alcohol by rectum. Same reaction shown by animal. Secretion began in 3 minutes.			
10:50-11:20		2.2	90	122
11:20-11:50		1.7	120	52
11:50-12:20 p.m.		0.7	70	41
		4.6 c.c.		
12:23-12:25	Attempted to give 2nd portion alcohol per rectum. Animal much agitated. Attempt unsuccessful.			
12:25-12:30	200 c.c. 5% alcohol by gastric fistula. Dog did not object.			
12:30- 1:00		3.5	119	59
1:00- 1:30		2.5	144	31
1:30- 2:00		0.9	—	58
		6.9 c.c.		

It is clear that in this experiment the discharge of pepsin was inhibited by the defence reaction of the animal. It is a familiar fact that such emotional reactions frequently inhibit alimentary conditioned reflexes for a considerable period. Since the secretion of pepsin is under the control of the vagus, we can say that the output of pepsin was small owing to inhibition of the vagal secretory centres, although there was still a flow of juice owing to the peripheral action of the alcohol.

Several experiments were performed in which it was attempted, by administration of atropine, to eliminate the vagal participation in the secretory effect of alcohol. The results of these experiments were, however, not very clear-cut. Large doses (0.3 mg. per Kg. of atropine sulfate) entirely abolished the secretion provoked by alcohol, chiefly perhaps by interfering with its absorption, since the stomach contained nearly the original volume of solution after 1½ hours. This is in agreement with the finding of Orbeli (6). Smaller doses of atropine diminished both the volume of the juice and the total output of pepsin, although the evacuation time of the stomach appeared to be not greatly lengthened.

DISCUSSION

Alcohol differs from all other chemical stimulants of gastric secretion in that it acts well from any part of the digestive tract. The composition of the juice secreted in response to alcohol (unless alcohol has become a conditioned alimentary stimulus) is very similar to that of the secretion provoked by histamine, *i.e.*, the acidity is high and the enzyme concentration low. Alcohol, therefore, like histamine, acts chiefly on the parietal cells. The primary secretagogue action of alcohol, like that of histamine, is a peripheral one, since it does not require the integrity of the extrinsic innervation of the pouch. Whether the antagonistic

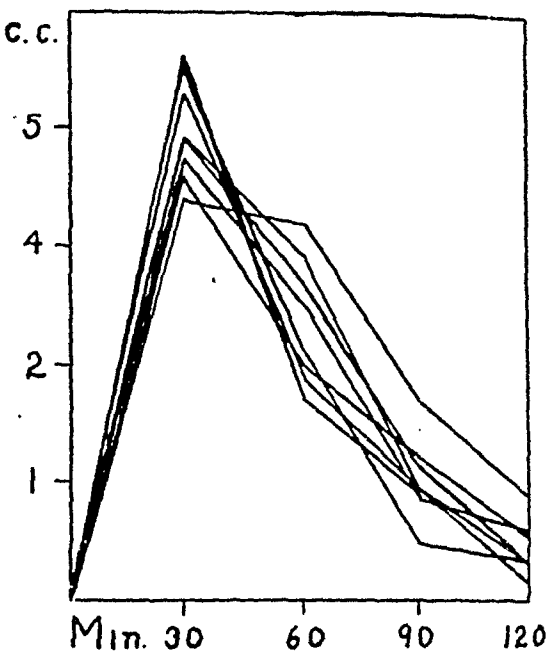

Fig. 2 (a). Volume of juice secreted (Pavlov pouch) after the introduction of 200 c.c. of 5 per cent alcohol into the stomach. 8 experiments.

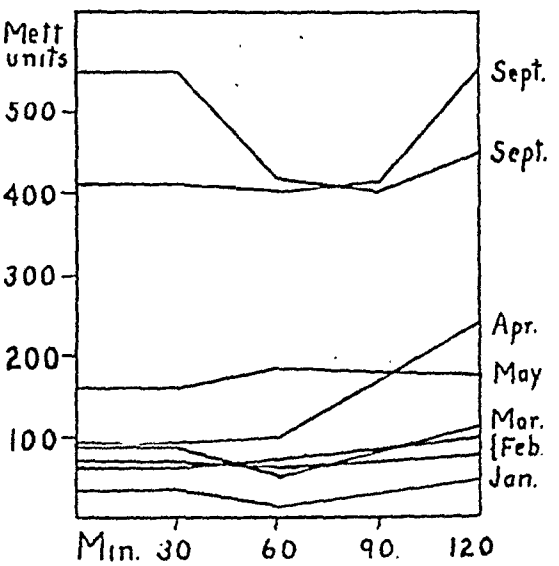

Fig. 2 (b). Concentration of pepsin in the gastric juice in the same 8 experiments.

effect of atropine is due merely to interference with the absorption of alcohol, or whether the intrinsic gastric nerves are involved in the action of alcohol, has not been determined.

From the practical point of view, it is worth while to note that positive alimentary conditioned reflexes may easily be formed with dilute alcoholic beverages. Even in the absence of such reflexes, alcohol through its peripheral action may improve a faulty digestion by increasing the flow of juice. If positive conditioned

from this is that he must recognize such women in time so that he will spare himself the misfortune of being responsible for the misery that will almost certainly follow the removal of all the remaining teeth. A toothless woman, prematurely aged and disfigured, and her long-suffering family will not soon forget to curse the name of any man who brings such misfortune upon them, especially when, as commonly happens, the Heberden's nodes, or the hypertension, or the buzzing in the ears, or the flatulent indigestion, for which relief was sought, continues unchanged.

Fortunately, after one has seen a few of these women, and an occasional man with the same trouble, it is not difficult to recognize the particular human type, and usually when encouraged to do so, they are very willing to keep their remaining teeth. Fortunately there usually are other ways of helping these people besides the one that is now so popular.

Walter C. Alvarez, Rochester, Minn.

THE ANTI-GIZZARD-EROSION FACTOR

THE apparent discovery (1) of an anti-gizzard-erosion factor may in time prove to be a requisite item for the complete understanding of the etiology and therapy of certain gastro-intestinal diseases. The observed facts may be briefly summarized as follows:

If young chicks are not fed properly they develop a "scurvy-like syndrome," characterized by anemia, hemorrhage, and by crater-like lesions in the lining of the gizzard. The syndrome is prevented by feeding pork liver, lung, kidney, oats and wheat middlings, the meat products being vacuum dried at 50° C. The anti-gizzard-erosion factor which is distinct from the anti-hemorrhagic factor, shows some variation in heat stability and is insoluble in ether and ethyl alcohol. When lung is digested with trypsin, the active principle may be extracted with alkali and precipitated with acid. Thus the active principle appears in the reticulin and not the gelatin fraction of the lung tissue. But when oats are fractionated, the active principle is distributed among three fractions which indicates that the principle is not necessarily related to a protein molecule.

According to Siegfried (2), reticulin is a special substance found not only in the lungs, liver and kidney, but also in the spleen, lymphatic glands and intestinal mucosa. Whether these latter tissues contain the active principle has not been determined, although Bird et al (1) observed slight or no erosions in two chicks fed gastric mucin granules. Chemically the supporting tissues of the body are related to mucin. Thus, it is possible that the growing chicken, requiring much material for the building of supporting tissue, will show gastric mucosal defects, when deprived of this essential factor, much more readily than an adult. It is also possible that the gastric defects are due indirectly to some hepatic disturbance, since the liver plays an important rôle in uronic acid (a building-stone of mucin and chondroproteins) metabolism (3) and since hepatic disturbances are not infrequently associated experimentally with gastro-duodenal ulceration (4). That is, the primary defect resulting from the deficiency of the anti-gizzard-erosion factor may be resident in the liver rather than in the gastric mucosa. The answers to such questions as those suggested and the probable practical worth of such information should stimulate thorough investigation of the chemical nature of the active principle and how its absence in the diet leads to the production of gastric erosions.

CHEMICAL MEDIATION OF NERVE IMPULSES AND THE GASTRO-INTESTINAL TRACT

THE Nobel prize in medicine for 1936 was awarded to Loewi and Dale for their work in developing the theory of chemical mediation of nervous effects. The theory maintains that the arrival of an impulse at the nerve ending liberates a chemical substance, which acts upon the receptive mechanism of the cell to produce excitation or inhibition, and that the same type of mechanism transmits the impulse across synaptic connections in autonomic ganglia. It should be of timely interest to call attention to the application of this relatively recent concept to gastro-intestinal problems.

Stimulation of the vagus nerve has been shown to liberate acetylcholine from the nerve endings in the stomach (1) and in the small intestine (2). It has also been shown that an adrenaline-like substance (sympathin) is liberated in the intestine and liver by the stimulation of their sympathetic innervation. Future work will in all probability confirm the generalization that sympathetic fibres to the gastro-intestinal tract liberate sympathin and that parasympathetic fibres liberate acetylcholine. However, important exceptions have been noted to this general principle in so far as the anatomic classification of the autonomic nervous system is concerned. For example, anatomically the sweat glands are said to be innervated by the sympathetics; yet these nerves liberate acetylcholine (4). The blood vessels are said to be sympathetically innervated; yet certain of the nerves passing to the blood vessels liberate both sympathin (adrenergic fibres) and acetylcholine (cholinergic fibres) (5). Were a similar situation to obtain in regard to the autonomic innervation of the intestinal musculature, an explanation might be provided for certain inconsistencies encountered in this field. For example, electrical stimulation of the parasympathetic (vagus) and sympathetic (splanchnic) nerves of the gastric musculature may result in either excitation or inhibition. Or, under more physiological conditions, the vagus nerves may produce either gastric motor inhibition, as when HCl is introduced into the duodenum (6), or gastric motor augmentation, as when hypoglycemia (acting centrally) is produced by insulin (7). It is conceivable that the body accomplishes these divergent results over the same nerve trunk by the selective utilization of adrenergic fibres in the first instance and cholinergic fibres in the second; in

sion disappears from the circulating blood in approximately 2-3½ hours. It was observed that the size of the fat globules did not exceed that of chylomicrons, assuring safety of the injections, as far as fat embolism is concerned.

To demonstrate the utilization of fat, if any, the following plan was conceived. Three puppies of the same litter, each weighing 6 lbs. (2.274 kg.) and measuring 18 in. (46 cm.) from nose to root of tail, were used. The surface area of each puppy has been computed to be .190 sq. m. according to the method of Cowgill and Drabkin. Taking the basal heat production at 790 cal. per sq. m. per day, makes the total basal metabolism of such a puppy 150 cal. per day.

One puppy, serving as a control, was placed on a diet consisting of fresh ground beef heart. The amount given daily was calculated to be equivalent to the number of calories required. Adjustments of the amount of food were made every few days according to the physiological increase of weight.

The second puppy was placed on a semi-starvation diet, viz. it was given 75% of the calculated requirement of calories in form of the same diet which was given the first puppy.

The third puppy was getting the same amount of food as the second and the deficit was covered with a corresponding amount of fat emulsion.

The first week subcutaneous injections were given daily. They were painful and had to be discontinued because the fat was apparently very slowly or not at all absorbed. After a few injections, made each time at a different place, the entire skin of the trunk became uniformly indurated as in elephantiasis, and seemed to be firmly attached to the deeper tissues, simulating an armor. The subsequent injections were given intraperitoneally. The semi-starving puppy died 32 days after the beginning of the experiment.

The puppy receiving fat injections survived. It did not have the appearance of a healthy animal; it had a poor appetite and was shy and not so lively and playful as the control puppy. Although it was gaining weight, the increase was less pronounced that in the control animal. It was sacrificed three months after the start of the experiment. The autopsy revealed an extensive aseptic peritonitis. There was a small amount of a slightly hemorrhagic serous exudate and numerous adhesions between the intestinal coils. Considerable fat deposits were found in the subcutaneous tissues. The histologic examination disclosed an abnormally high fat content of the lungs and heart muscle while the spleen, liver, brains, omentum, mesenteric lymph glands and retrobulbar tissue of the orbits had a normal aspect. It was surprising to find such extensive pathologic processes in the peritoneal cavity as the animal, although apparently not healthy, remained alive for three months and did not seem to be losing ground until it was sacrificed. The experiment was repeated on another puppy with identical results: intraperitoneal injections caused an aseptic peritonitis.

This experiment showed that 1. subcutaneous injections of fat emulsion are not feasible; 2. intraperitoneal injections cause an aseptic peritonitis; 3. fat emulsion is apparently absorbed from the peritoneal cavity; 4. fat injected intraperitoneally sustains the life of a semi-starving dog.

In view of the pathologic lesions following intraperitoneal injections, this mode of introduction of fat emulsion could not be considered for therapeutic purposes. The veins in small puppies are too small to allow daily intravenous injections, particularly because a heavy gauge needle must be used. Therefore another experiment was planned. Two adult dogs were used, one weighing 11.25 and the other 10.8 kg.; the first, serving as a control, was completely starved; only water was offered. The other was also completely starved, but in addition to water, daily intravenous injections of 60 c.c. of the fat emulsion were administered. Several times the fat was injected into the femoral artery. All the injections were well tolerated. They were apparently not painful and no thrombi were noted.

TABLE II

Days of starvation	Weight of Control Animal	Weight of dog receiving fat injections
1	11.25 kg.	10.80 kg.
6	10.90	9.90
9	10.60	9.40
12	10.10	9.00
16	9.20	8.55
19	8.70	8.30
22	8.40	8.10
27	7.90	7.60
28	7.70	7.60
31	6.52	6.75
32	6.30	6.55
34	6.15	6.50
36	6.00	6.45

A paradoxical phenomenon was observed the first two weeks: the animal receiving the injections lost weight more rapidly than the control dog, as can be seen from Table II. The amount of water consumed by each animal was approximately the same so that the difference could not be explained on this basis. We can offer no explanation for this observation. However, after the first 16 days the average loss of weight of the dog receiving injections was smaller than that of the control animal. As can be seen from the accompanying table, the control dog lost 3 kg. between the 6th and 27th starvation days and the other only 2.3 kg.

Between the 6th and the 36th day the losses were 4.90 and 3.55 kg. respectively. The control dog died on the 36th day of starvation. Injections were continued in the other dog for ten days more, during which the animal lost 0.45 kg. This dog weighed at the start of the experiment 0.45 kg. less than the other; in spite of this it survived the control. Throughout the whole experiment the dog receiving the injections was more vigorous and lively than the control. A period of ten days was deemed to be sufficiently long to eliminate the possibility of a merely accidental survival.

To corroborate the findings, the whole experiment was repeated on another pair of dogs, one weighing 10.9 and the other 10.2 kg. The latter was given intravenous injections of the emulsion daily. The control animal died on the 31st day of starvation, while the other dog lived on; injections were continued for

additional two weeks before the experiment terminated. During the starvation period this dog lost 4.2 kg. and the control 4.6 kg.

It is evident that the quantity of fat administered in these experiments was able to consistently prolong the life of otherwise starving animals and to reduce the eventual weight loss. As an emergency measure it seems that parenteral administration of fat emulsion might have sufficient virtue for clinical trial. Danger from fat embolism is virtually non-existant and all lines of evidence point clearly to the fact that intravenously administered emulsions are utilized.

SUMMARY

1. By employing the process of homogenization it is possible to prepare a stable sterile fat emulsion which, if administered parenterally, produces no fat embolism.

2. Subcutaneous route is not recommended because the injections are painful and the emulsion is absorbed very slowly.

3. Intraperitoneal route is not available because the fat emulsion causes an aseptic peritonitis with resulting adhesions.

4. Intravenous infusions are well tolerated by dogs.

5. Intravenous infusions prolong the life of semi-starving and completely starving dogs.

6. The fact that a completely starving dog receiving daily injections of a fat emulsion survives the starving control, serves as a definite proof of utilization of the introduced fat.

7. Although results of animals experimentation can be applied to human pathology only with a great caution, the results of the above described observations prove that an intravenously administered emulsion of fat is available for metabolic purposes.

The author makes grateful acknowledgement to Dr. M. B. Visscher, Head of the Department of Physiology, for his invaluable suggestions.

Pruritus Ani: A Preliminary Report of One Hundred and Thirty-Three Cases Using Triple Distilled Water*†

By

HARRY E. BACON, B.S., M.D., F.A.C.S.
PHILADELPHIA, PENNSYLVANIA

PRURITUS ani is as fascinating as is its treatment, at times, discouraging; for this reason any form of therapy carrying with it a surprising percentage of temporary and permanent cures is worthy of consideration.

In this presentation, it is not our purpose to recommend the use of distilled water as a routine procedure, but rather to present our results following the use of injections of triple distilled water. Credit is given Hanes (3) for first employing this treatment in pruritus ani, although Davis (2) has since used it extensively with most gratifying results. The latter believes that the tissue changes are chemical, and not bacterial, and that the introduction of double distilled water dilutes the chemicals, aids in their absorption and in the excretion of those which he thinks tend to accumulate in the anal and perianal skin and induce pruritus. Tashian (5), on the other hand, believes that triple distilled water stimulates the defense cells of the reticuloendothelial or histiocytic system.

METHOD

The method we employ (4), which is a modification of that primarily suggested, is as follows: The patient is placed in an exaggerated left lateral position. The quadrant causing the most distress, or the one appearing most inflamed, is selected for the first injection. The area is swabbed briskly with alcohol or tincture of green soap and is dried with sterile gauze. A point just beyond the periphery of the pruritic zone is selected and touched with tincture of iodine. This is wiped off with alcohol, and when the skin has dried an intradermal wheal is made with one per cent novocain, using a small hypodermic needle. A 21 gauge needle, two and a half inches in length, to which is attached a syringe containing one c.c. of novocain, one per cent, is slowly advanced beneath the pruritic skin. At this point the novocain is deposited. The needle is held in situ and a 10 c.c. syringe containing 10 c.c. of triple distilled water substituted. The contents are slowly injected until the entire amount is used. Should pain or discomfort attend its introduction, injection is suspended for a few seconds. Each quadrant is similarly treated at intervals of three or four days, until a series of eight injections has been given, or until the patient is symptom free. In over 50 per cent of our cases, only five c.c. were employed, instead of the usual quantity.

RESULTS

Over a four-year period ending with 1933, 133 cases were treated in the clinics of the Temple University and Graduate Hospitals and in private practice (1). In this group there were 85 males and 48 females, with an average of 41 years. The duration of symptoms

*From the Proctologic Department of the Temple University Hospital and the Graduate Hospital, University of Pennsylvania.
†Read before the meeting of the American Proctologic Society, Kansas City, May 9, 1936.
Submitted January 19, 1937.

ranged from nine months to 23 years. Of the 133 patients, 91 had had one or more operations on the anorectum without relief.

A study of the charts for these cases reveals that the average number of injections administered was nine, the extremes being three and 23, as shown by the following table:

4	patients	received	3	injections
4	"	"	4	"
18	"	"	6	"
41	"	"	8	"
38	"	"	10	"
11	"	"	12	"
2	"	"	13	"
8	"	"	14	"
4	"	"	16	"
1	"	"	18	"
1	"	"	20	"
1	"	"	23	"

In three cases treatment was interrupted because of the development of ischiorectal abscess. This occurred when this form of therapy was first begun, and we felt it was the result of improper cleansing. Since iodizing the skin prior to making the injection has been instigated, no concurrent infection has been observed. Of the remaining 130 patients, 42 did not return for a check-up, or did not reply to our questionnaire. Thirty-nine of these 42, however, were symptom free at the time of their discharge from clinic. The reports on 88 cases, representing a lapse of between two and a half and three years, are as follows:

Symptom free (cured)	27 or	30.7%
Improved	56 or	63.6%
No Relief	4 or	4.6%
Worse	1 or	1.1%
	88	100.0%

CONCLUSIONS

A preliminary report of 133 cases treated with triple distilled water is offered. Following a period of 30 to 36 months, 94.3 per cent of the above cases were benefited. Of these, some were completely symptom free, and some were improved.

In those cases where the associated pathology has been removed or corrected without effect, or in which the etiology is involved, we feel that this form of therapy is worthy of a definite place in our armamentarium for the correction of pruritus ani. Its results to date certainly justify any further study that may be needed to develop the plenitude of its possibilities.

Renocolic Fistula*

Report of an Instance Roentgenologically Simulating Carcinoma of the Colon

By

MAURICE FELDMAN, M.D.
BALTIMORE, MARYLAND

RENOCOLIC fistula is an extremely rare complication of renal disease. Its occurrence has been known for many centuries. A review of the literature reveals very few references regarding this condition. Hippocrates mentioned a case of rupture of a renal abscess into the intestines. Since then but few single case reports have been recorded. The most complete early study of renal fistulae was made by Rayer (1), who cited a number of authors reporting cases on this subject. Mertz (2), in 1931, summarized all reported cases in the literature and recorded two of his own. Vermooten and McKeown (3) more recently reviewed the literature, added another case. The intimate relationship between the colon and the kidneys is an important factor in the formation of fistulous communications between these two organs.

Renocolic fistula are more commonly located on the right side, which is no doubt due to the closer relationship of the right kidney and colon than that on the left side. The majority of cases reported in the literature were found to involve the right kidney. However, a few cases have been reported occurring on the left side. D'Allaines and Roufliac (4) report a case of a fistula between the left kidney and colon; and Roman (5) recently reported another case of a fistula between the left kidney and the colon with external fistulization, with extensive tuberculosis of the kidney.

The primary etiology in most instances is due to a pyelonephritis, producing a secondary perirenal inflammation, suppuration with subsequent necrosis and abscess formation and finally perforation into the colon. Of 20 cases collected from the literature by Vermooten and McKeown (3) 8 were associated with renal calculi, 2 with tuberculosis, while 13 or 50% of the cases were described as having a pyelonephrosis.

* From the Department of Roentgenology, Sinai Hospital, Baltimore, Maryland.
Received for publication November 17, 1934.

Fig. 1. A large massive irregular filling defect is shown at A, involving the ascending colon, presenting all the characteristic roentgen signs of a carcinomatous growth. Note the irregular fistulous tract at B leading towards the spinal column.

In 12 cases, an acute or chronic suppurative perinephritis was observed.

It is of interest to emphasize that in the majority of cases the original source of infection occurred in the kidney. In reviewing the literature of collected series of cases it must be pointed out that in not a single instance was the primary lesion observed in the bowel.

In the diagnosis of renocolic fistula, the X-ray affords one of the most valuable measures in determining the exact nature of this complication. Before the advent of roentgenography, the diagnosis of renocolic fistula was never made clinically. It was then made either at autopsy or by surgical procedures. In recent years, however, a few cases of this complication have been reported which were diagnosed by means of the X-ray. The fistulous communication had been encountered by pyelographic studies of the kidneys. In Blanco (6), Barnes (7), and Vermooten and McKeown's cases, the roentgen examination of the genitourinary tract revealed evidence of this complication. In reviewing the available recent literature, the roentgen diagnosis in most instances had been made by means of the routine retrograde pyelographic studies. In no instance was a case recorded in which the diagnosis was made by a barium enema examination, with the exception of Riaboff's (8) case, in which the roentgenogram revealed a filling defect in the first portion of the transverse colon.

In this presentation, a second case of renocolic fistula is recorded in which the barium enema gave the first clue as to the true nature of the condition. The barium enema revealed a large irregular filling defect in the ascending colon, presenting all the characteristic roentgen signs of a malignant growth with

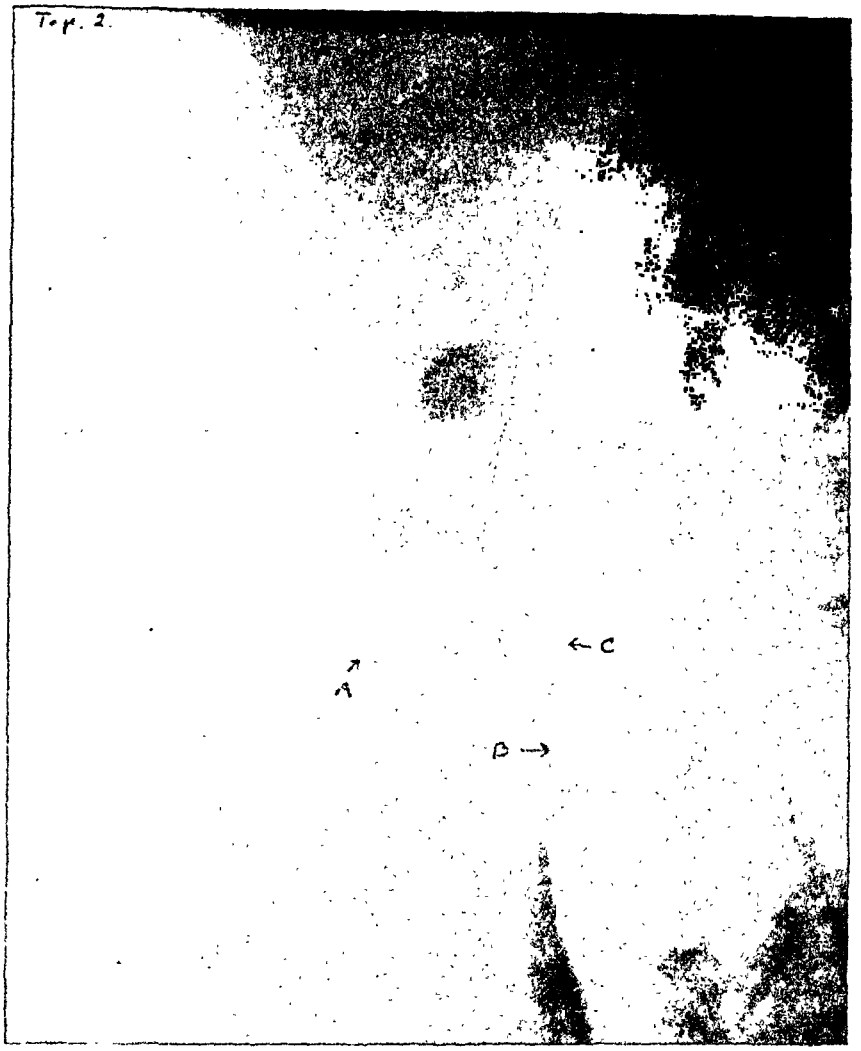

Fig. 2. Retrograde pyelogram illustrates the poor filling of the kidney pelvis and faint outline of the inferior calyx at A. The superior calyx is dilated and blunted. Note the pressure defect upon the upper ureter at B produced by the mass. A ureteral kink is shown at C.

a large mass on the right side. On close observation, an irregular narrow channel could be seen leading from the colon toward the mass which suggested a fistulous tract. A pyelographic study was also made in this case, which presented evidence of a pyelonephritis. The fistulous tract is not visualized on the pyelogram, which indicated that the communication existed between the colon and perinephritic abscess. At operation a large retroperitoneal inflammatory tumor was found with multiple perinephritic abscesses of the right kidney. A fistulous communication was observed between the kidney mass and the ascending colon.

SUMMARY

A case of renocolic fistula is reported, presenting all the roentgenographic signs of carcinoma of the ascending colon. This is the second case to be recorded as far as could be ascertained from the literature in which a barium enema method of examination revealed roentgen evidence of extensive colon involvement with a fistulous tract leading into an inflammatory mass on the right side. The roentgen ray offers the only means of establishing a preoperative diagnosis.

A Study of the Cardia*

By

WERNER ZELLER, M.S.

and

G. E. BURGET, Ph.D.

PORTLAND, OREGON

AN increasing clinical interest in dysphagia and obstructions at the cardia has stimulated a renewal of efforts to study the sphincter under normal and well controlled experimental conditions. The term "cardiospasm" has been used to indicate all types of obstructions until relatively recently. The work of Hurst and Rake (1) aroused new interest in this clinical condition by showing that a failure of the relaxing mechanism (*achalasia*) alone could constitute an obstruction to the passage of food. Their conclusions were made after studying post-mortem material from patients who had suffered from functional obstruction at the cardia. There was no hypertrophy of the sphincter but a degeneration of Auerbach's cells seemed to have taken place.

Because of the mechanical difficulty of keeping a balloon in the cardia, registration of its activity for any continuous period has met with failure. The balloon either rises into the esophagus or slips into the stomach. Carlson, Boyd and Pearcy (2) used a rubber plug placed on the stomach side of the cardia, and attached the cardia balloon so that tension could be placed on the plug, thus holding it snugly to the lower surface and maintaining the balloon in the cardia and lower esophagus. While this apparatus could be used on the anesthetized animal to study tonus changes and the effect of nerve section and stimulation, it was used in only one animal with a permanent gastrostomy and esophageal fistula. For a comprehensive survey of the literature on the innervation of the esophagus, cardia and stomach, together with the effects of nerve section, the reader is referred to the work of McCrea (3).

PROCEDURE

Dogs with gastric and esophageal fistulae were used. They were trained to lie quietly without restraint on a table made comfortable by a pad. All animals were healthy and in good physical condition; no anesthesia was used in making any of the observations here reported.

Esophageal fistulae were made about one inch below the level of the cricoid cartilage. Under aseptic technique a mid-line incision was made in the neck, the ribbon muscles were separated from the deep tissues and the esophagus pulled up to the left of the trachea. Care was taken to prevent injury to the recurrent laryngeal nerve. The walls of the esophagus were then sutured separately to the fascia overlying the ribbon muscles and to the skin before making the ostium. No special postoperative care was necessary, and the animals were able to swallow liquids and solids with a minimum of leakage from the fistula.

The gastric fistulae were made at a separate operation under ether anesthesia. The abdomen was opened by a right rectus incision. A segment of jejunum or ileum about 7 or 8 cm. long with a suitable blood supply was resected. The distal end was anastomosed to an opening made in the anterior wall of the fundus of the stomach. The proximal end was brought to the surface through the original incision and sutured to the peritoneum, muscle and skin in separate layers. The continuity of the gut was restored by a closed, end-to-end anastomosis as described by Martzloff and Burget (4), and the abdomen closed. This type of fistula has been found to have distinct advantages over the usual gastrostomy. Since direction of peristalsis is from outside inward, any material which is forced into the segment of the gut as a result of increased intragastric pressure is swept back into the stomach. No leakage of gastric juice from the fistula occurs, and therefore no care is necessitated.

For recording activity of the cardia, a thin layer of sponge rubber was wrapped about the perforated end of a rather rigid tube and covered by a delicate balloon. The tube extended through the length of the balloon, which was 3 cm. long and 1 cm. in diameter. This was placed in the cardia through the esophageal fistula. The cardia can easily be felt and the balloon held in place throughout the experiment. This balloon was never distended with air. It is soft and easily compressed with the sponge rubber holding sufficient air for recording any change in the tonus of the cardia when attached to a sensitive tambour. This balloon produced no discomfort when in place and was so flexible as to permit a record of slight changes of tonus in the sphincter. In early experiments a second balloon of thin rubber attached to a very small tube was placed in the esophagus well above the cardia. This balloon was attached to a tambour by way of a T-tube. When the operator desired to stimulate the esophagus, he had only to blow in the arm of the T-tube, distend the small balloon, and initiate a peristaltic wave. The stimulus was recorded by the tambour. Later it was found desirable to use this balloon without the T-tube to record peristalsis of the lower esophagus and use a third balloon above this one, unattached to a tambour and used solely for stimulating purposes. At the time of blowing into the balloon, the operator recorded the stimulus by a key and signal magnet. While this set-up might seem unphysiological, the tubes were small and did not irritate the esophagus to the extent of producing reflex contractions, nor were there any signs of discomfort displayed by the animal. A larger balloon was placed in the stomach by way of the gastric fistula and connected with a chloroform manometer for recording activity of the fundus and body. This balloon was distended with air sufficiently to record pressure changes but not enough to elicit contractions.

Observations usually were made ten to fifteen hours after feeding but in some instances earlier records were taken. All animals had gastric and esophageal fistulae as described. Records were made under the following additional conditions: normal; one vagus sectioned in cervical region; both vagi sectioned in cervical region; double vagotomy in the thorax; double vagotomy in the thorax with one vagus sectioned in the cervical region; both vagi and both splanchnics sectioned in the thorax; sympathetics sectioned as fibers approached the cardia by way of the

Submitted December 28, 1936.

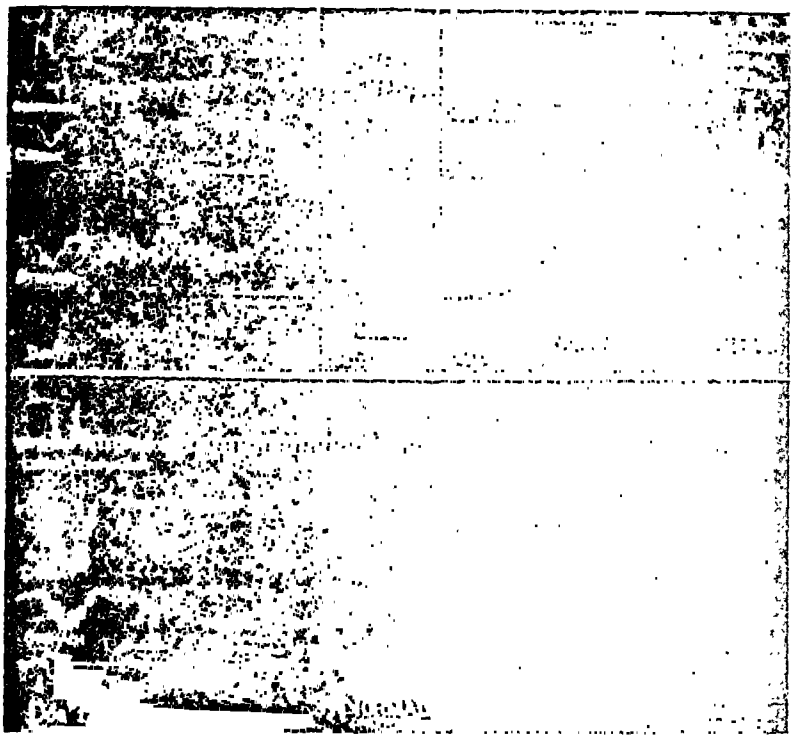

Fig. 1. Tracings before nerve section. That taken from dog 7 shows the cardia relaxation and the lower esophageal activity when the cardia balloon was drawn to this position. The effect of swallowing is shown (dog 13). In tracing from dog 3 the effect of continuous activity of the esophagus on cardia and stomach is made clear. The lower half of this figure (dog 17) shows remarkable relaxation. Here a balloon recorded activity of the lower esophagus also. A light stimulation and even a swallow did not produce a wave that traveled down to the cardia, or if it did, it was so weak as to not record.

left gastric artery; sympathetic section together with double vagotomy in the thorax.

RESULTS

Findings on the Normal Animal: When the balloon is lowered into the cardia by way of the esophageal fistula, the operator can definitely feel when the cardia is passed. On pulling back from the stomach into the lower esophagus, a resistance is felt which is suddenly released as the balloon passes through the cardiac sphincter. The observations of Carlson and Luckhardt (5) were confirmed in that the tonus of the cardia is usually increased with hunger contractions of the stomach. Following an act of deglutition, the cardia and stomach are seen to begin relaxation while the peristaltic wave is still high in the esophagus. The height of relaxation is reached as the wave approaches the cardia. Following this relaxation, there is usually a temporary rise in tonus of the sphincter. Exactly comparable results are seen following inflation of the balloon in the upper part of the esophagus. If a series of secondary peristaltic waves were elicited by the distended balloon, a marked fall in tonus of the cardia is maintained throughout the esophageal activity (Fig. 1).

An interesting observation was made in one instance where the cardiac balloon had been pulled into the lower esophagus; the stomach was seen to relax in response to a peristaltic wave in the upper esophagus, but this wave was not picked up by the cardiac balloon. It was this observation that led us to place an extra balloon in the esophageal fistula to record the activity in the lower esophagus. By this means a check could be made upon the ultimate termination of the wave initiated in the upper esophagus. With very weak distention of the esophageal balloon a wave may be elicited and start to pass down the esophagus. The cardia and stomach relax, but no evidence of the wave having reached the lower esophagus can be obtained. With stronger distention of the upper balloon, the wave traverses the length of the esophagus and is definitely recorded by the lower esophageal balloon with the cardia and stomach relaxed as before (Fig. 1). That this relaxation in the cardia is absolutely independent of diaphragmatic activity is seen in Fig. 3, which was taken on a hot day when the dog was panting. The respiratory movements are recorded by the balloon in the lower esophagus.

Effects of Vagus Section in the Neck: Unilateral section of the vagus in the neck was carried out on six dogs. In three the left vagus was cut; and in three the right. Tracings were taken as early as four hours after the operation (Fig. 2). During the first twenty-four hours the esophagus is partially paralyzed and somewhat atonic. Although relaxation of the cardia can be elicited upon distention of the esophagus, the pressure necessary is greater than that re-

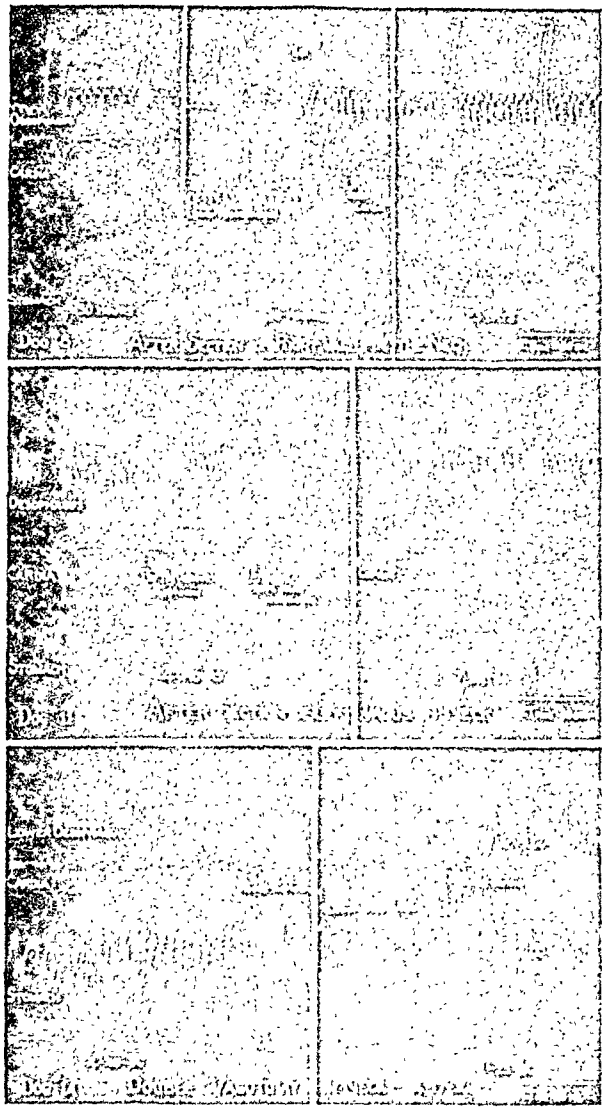

Fig. 2. In tracing for dog 8 following section of right vagus in neck, a normal response is given. Dog 11, no effect from section of left vagus in neck. Section of both vagi (dog 14) results in paralysis, tracing showing respiratory curves.

quired in the normal animal, and the relaxation of the cardia is not as marked. The tonus is regained within a few days, and relaxation follows swallowing or distention of the esophagus, apparently as well as before the nerve section. The threshold, however, remains a little higher than in the normal animal. The type of response and relative time relations are little if at all altered. There seemed to be no difference in the effect produced with regard to section of right or left vagus.

Section of both vagi in the neck was performed on three dogs, resulting in complete paralysis of the esophagus. Under this circumstance it is impossible to initiate a wave in the esophagus. The cardiac balloon, when pushed through the cardia into the stomach, could be returned to the esophagus with less resistance than was present before the operation. In the course of a few days the cardia regains some of its tone, but never was it possible to elicit relaxation by distending the esophageal balloon. These dogs, of course, are difficult to maintain since they aspirate food into the lungs and die of pneumonia. One of our dogs lived fifteen days. All showed hypertonic stomachs in the course of a few days. This was especially noticeable when it was attempted to feed them by way of the gastric fistula, food would often be forced either back through the gastric fistula or into the esophagus. This hypertonicity seen in the stomach did not appear to be present, at least in high degree, in the cardia. Hunger may have been a factor.

Effects of Sectioning the Vagi in the Thorax: There were nine dogs in this group, five of which had the vagi sectioned immediately (2-3 cm.) above the diaphragm and four higher at the lung roots (6 to 8 cm. above diaphragm). The approach was made through the left side, posteriorly, between the eighth and ninth ribs. An incision was made about 6 cm. long parallel with the ribs. After entering the thoracic cavity, a small spreader was used to hold the ribs apart. The lung fell away and revealed both vagi—the left one anterior and right one posterior to the esophagus with the branch from the left coming down to join the right one about one inch above the diaphragm. Both vagi and the connecting branch were grasped with hemostats and sections of nerve removed by cutting on either side of the clamps. The thorax was then quickly closed and the dogs all made an uneventful recovery. Tracings were taken twenty-four hours after the operation and at intervals for six months. In both high section (dog 11) and sectioning immediately above the diaphragm (dog 1) the relaxation mechanism in the cardia and stomach was unaffected. There was no evidence of spasm or paralysis in any of these animals. It is impossible to detect any difference in the type of relaxation or time relations as compared with the normal dog either immediately or several months after operation (Fig. 3). (Dog 11 had vagi cut low at first, then resectioned high in thorax eleven months later). These animals also showed a relaxation of the cardia and stomach when a weak stimulus was applied to the upper esophagus without showing a peristaltic wave in the lower portion. Stronger distention produced a wave which was recorded by the lower esophageal balloon with the usual relaxation of the cardia and stomach.

Vagi Sectioned in the Thorax with One Cut in the Neck: Three animals thus operated upon showed no apparent change in the type of activity in the cardia and stomach following peristalsis in the esophagus. They did show, however, a lowered irritability as was seen in animals with only one vagus sectioned in the cervical region (Fig. 4).

Effects of Section of Sympathetics: The sympathetic supply to the cardia, as described by Knight and Adamson (6), was sectioned in two dogs. Through a left rectus incision the left gastric artery was exposed high up on the lesser curvature of the stomach. It was freed and ligated along with its vein. The esophageal branch of the artery was dissected free, along with a bundle of nerve tissue lying along side, and

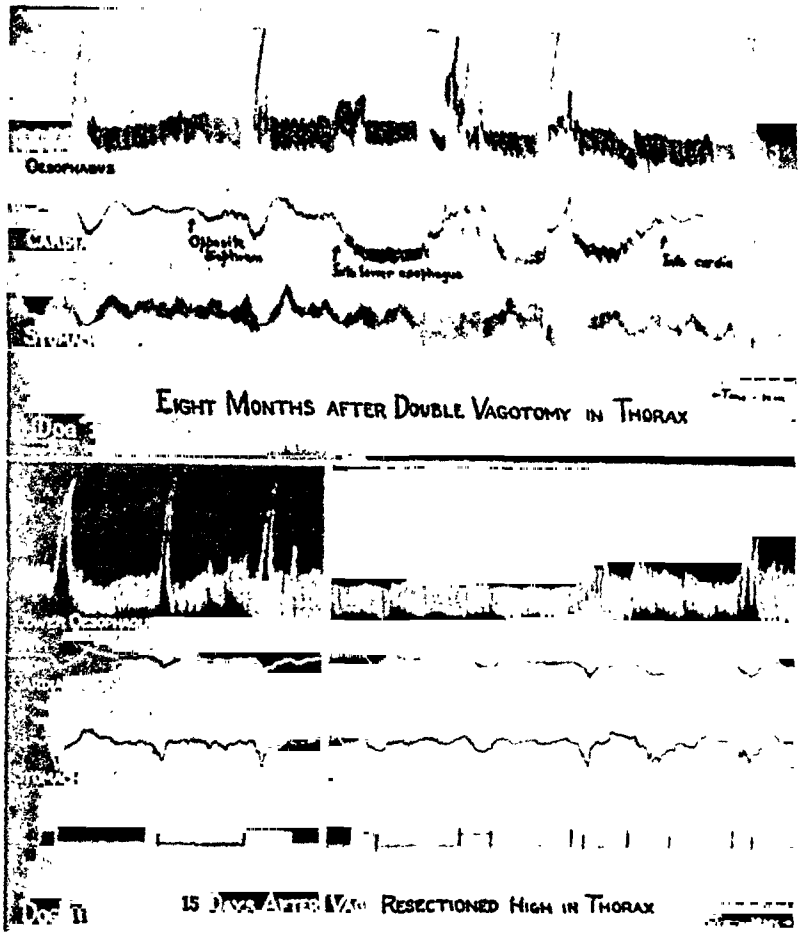

Fig. 3. Upper tracing vagi cut above diaphragm with an active cardia. Lower tracing shows effect when nerves were sectioned as high in the thorax as possible —good relaxation of cardia and stomach. Here a balloon in the lower esophagus caught the wave on strong stimulation but on light stimulation there is no indication of a wave in the lower esophagus. Respirations were rapid and completely without effect upon the cardia relaxation.

pulled over to the dog's right. The deep aspect of the left gastric artery was thus exposed and many strands of nerve tissue were found passing from the coeliac ganglion to the lower end of the esophagus. These were all divided at their peripheral ends. The section was carried centrally until the left side of the coeliac axis was exposed. The left gastric was then ligated at its origin and the segment removed along with the mass of nerve tissue that had been dissected free. This operation was followed by no immediate or late spasm or paralysis of the cardia, nor was the tone of the cardiac sphincter appreciably altered. Again the cardia and stomach showed relaxation when the upper esophageal balloon was distended whether or not a wave of the esophagus was picked up by the lower esophageal balloon (Fig. 5). Likewise two dogs with the splanchnic nerves cut in the thorax continued to give normal cardiac relaxation.

Effects of Sectioning Both Vagi and Sympathetics: Three dogs were prepared with a combination of operations—two with double vagotomy in the thorax and sympathectomy in the abdomen as above described, and one with double vagotomy in the thorax together with splanchnicectomy. In these animals gastric motility was reduced but returned to normal in the course of a few weeks. The cardia and stomach continued to relax following initiation of a wave in the esophagus. While the relaxation of the cardia seemed complete, probably relaxation of the stomach was less than normal. The nature and time relations of the relaxation were unaltered so far as could be determined (Figs. 6 and 7).

In one dog the esophagus was cut across and both ends brought to the skin in the neck. A stimulating balloon could be used in the upper segment while a recording balloon was in the lower esophagus and one in the cardia. Stimulation in the upper segment brought about the usual esophageal wave and relaxation of the cardia. The vagi were now cut high in the thorax of this dog, and twenty-four hours later a test

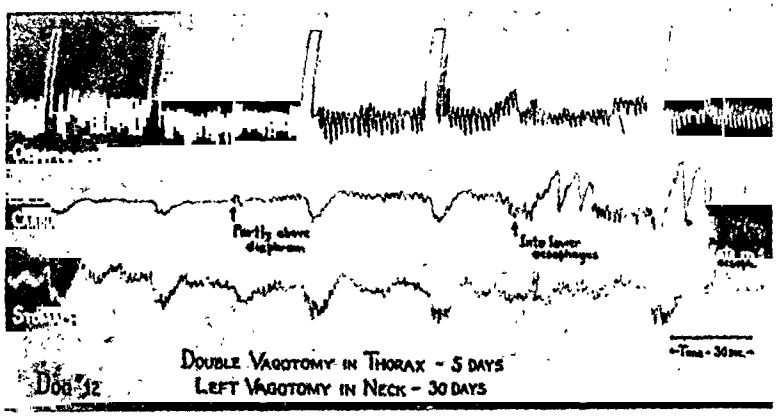

Fig. 4. Cervical section of one vagus following double vagotomy in the thorax leaves an apparently normal reflex.

showed both a wave in the esophagus and relaxation of the cardia. Swallowing produced the same effect. Even upon a light stimulus to the upper segment relaxation of the cardia took place without an apparent wave in the lower esophagus. This observation indicates the sensitivity of the inhibitory reflex in the cardia and implies the presence of long vagus fibers along the esophageal wall that are not reached in sectioning the trunks of the nerves, or an intrinsic mechanism that is dependent upon an outward flow of central impulses over the vagi.

In an attempt to destroy any long vagus fibers leaving the trunk in the thorax, the nerve trunks were freed from the esophagus over an area from the diaphragm to the lung roots without being sectioned. Following recovery from this operation, the dog showed normal relaxation of the cardia and stomach.

This mechanism is not paralyzed by atrophine. Dogs were given as high as 3 mg. atropine sulphate without affecting the inhibitory reflex of the cardia. However, the stomach response was materially reduced or abolished by this dosage.

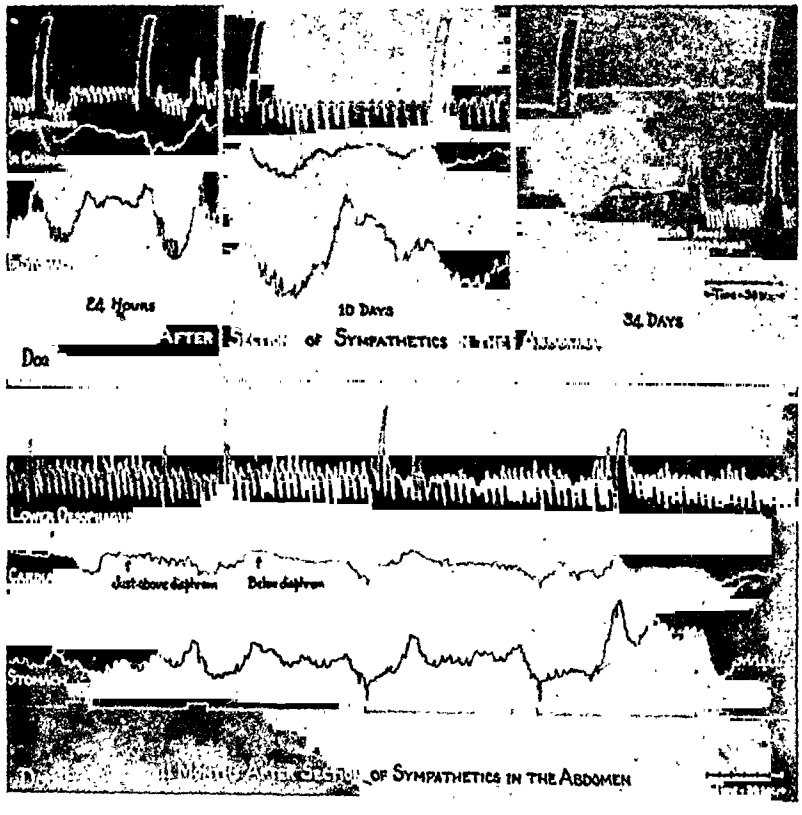

Fig. 5. Tracing from dog 7, 24 hours, 10 days, 34 days, and 11 months after section of the sympathetic fibers to the cardia as described by Knight. The relaxation reflex is still present.

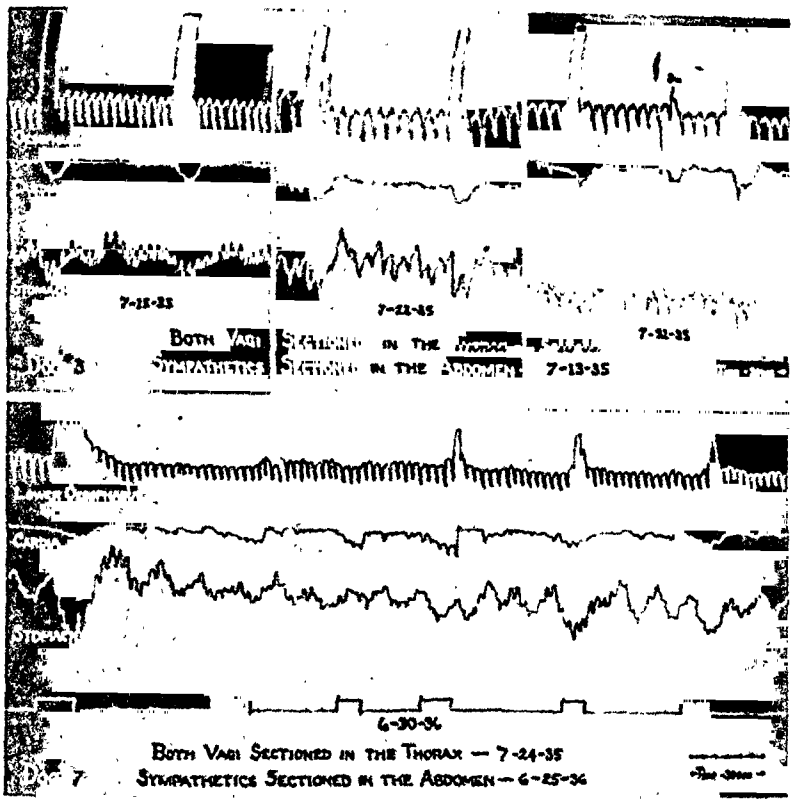

Fig. 6. Tracings following section of the vagi in the thorax together with sympathetic section in abdomen. There can be no doubt that the mechanism which brings about this reflex inhibition is still present.

Further investigation of this problem is being made by way of a histological examination of the esophagus for long nerve fibers and the possibility of a myenteric plexus. While studying the tonus of the esophagus and cardia in connection with hunger contractions, Carlson and Luckhardt (5) expressed the opinion that the dog's esophagus did not possess a myenteric plexus. If this is confirmed, the necessary impulses must be carried by way of long vagus fibers in the viscus. This, of course, would bring up the question as to the extent vagus impulses have been cut off in all of those experiments by physiologists where the activity of these nerves was supposed to have been removed by sectioning the trunks above or below the diaphragm.

DISCUSSION

Our observations as regards paralysis of the esophagus following vagus section in the neck confirm those of Kronecker and Meltzer (7) working on rabbits, but we failed to see a marked cardiospasm in the dog. Cannon (8) found that section of the vagi in the neck in cats leads to an increased tonus of the cardia lasting several days. The smooth muscles at the lower portion of the esophagus in these animals was ineffective in forcing food through the cardia. Kelly (9) cut the vagi in the cervical region in cats and noted a retention of food in the esophagus by means of the fluoroscope. He felt the increased tonus of the cardia prevented passage of the food. Knight has recently reinvestigated the innervation of the esophagus and cardiac sphincter in an attempt to obtain a rational basis for the surgical treatment of achalasia. Upon sectioning the vagi in the cat, Knight (10) obtained a partial obstruction at the cardia which was maintained, resulting in a greatly dilated esophagus. He found that if the sympathetic fibers were sectioned, this obstruction did not occur or if present, was removed. He attributed this effect of vagus section to a failure of the sphincter to relax under the peristaltic wave of the esophagus.

In 1883 Kronecker and Meltzer (7) noted relaxation in the cardia following repeated acts of deglutition. They assumed this to be a central inhibition of vagus motor tone to the cardia. A similar phenomenon was observed by Langley (11) in rabbits. Cannon and Lieb (12), while working on cats, made the observation of a receptive relaxation in the cardiac portion of the stomach. They noted that the stomach began to relax before the waves in the esophagus had time to reach the stomach, and state — "the vagus impulses anticipate the esophagus needs by a good margin." Section of the vagi in the neck abolished this inhibition, and they concluded it was dependent upon the intact vagi. A similar observation was made by Veach (13) in acute experiments on cats under anesthesia. Peristalsis of the lower end of the esophagus was followed by a receptive relaxation of the

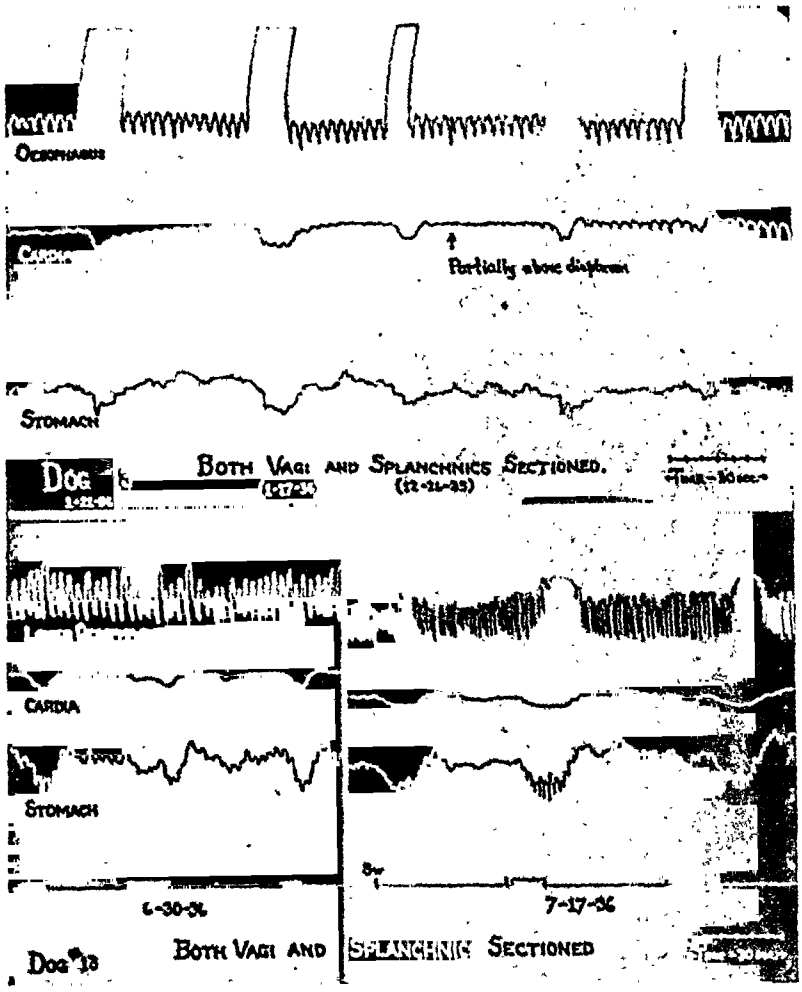

Fig. 7. Section of both vagi and both splanchnics in the thorax leaves the reflex intact. Note relaxation of the cardia and stomach upon swallowing in lower tracing.

stomach. Bilateral section of the vagi in the cervical region abolished this relaxation. He suggested that the myenteric plexus may not function as regards this phenomenon and the intact vagi are essential. Our observations on dogs, which animal has comparatively little smooth muscle in the esophagus, confirm the disappearance of this reflex following high vagus section, but in this animal we may assume that no peristaltic wave under these circumstances arises even in the lower esophagus. Consequently, if this phenomenon of relaxation is dependent upon a reflex process in the esophagus, the key to the mechanism has been lost when the esophagus is paralyzed.

That the vagi exercise a regulatory function as regards the activity of the cardia is agreed by all investigators. Krehl (14) cut the vagi below the diaphragm in dogs and found the esophagus to have lost a part of its tone and the cardia to be patulous. He tested the tonus of the cardia by inserting a stomach tube through the opening by way of a gastrostomy. Sinnhuber (16), who also worked on dogs, concluded that section of the vagi above but close to the diaphragm renders the cardia atonic. These observations differ from those of Knight, who felt section of the vagi merely removed the powers of inhibition in the sphincter. In all of our animals with vagi sectioned in the thorax, the cardia seemed to remain practically unaffected in tone and never was the power of relaxation lost. It may be, however, that this animal differs in this respect from the cat used by Knight. He felt that when the sympathetics were also sectioned, the cardia was again free to relax under intrinsic control. The influence of the sympathetics did not seem to be of importance in this respect in our observations. Whether the splanchnics were sectioned or the sympathetic fibers cut about the left gastric artery, relaxation of the cardia and stomach were little affected. This was true whether or not the vagi were intact or sectioned in the thorax. This would lead one to conclude with M'Swiney (15) that the cardia and upper portion of the stomach are closely related in function and that the cardia is less associated with changes of tonus in the esophagus. The separateness of the activity of the cardia has impressed us in these observations. It does not seem necessary that a peristaltic wave actually approach the cardia in order for

that sphincter to undergo inhibition. On the other hand it does seem necessary that some sort of reflex be initiated in the esophagus before this relaxation actually takes place. We are forced then to appreciate the dependence of its activity upon the extrinsically innervated esophagus. There are two possibilities in which this correlation of activity could take place under the circumstances of our experiments. Either section of the vagi in the thorax leaves connection along the esophageal wall with the vagus above the section that is effective in carrying out the reflex (long vagus fibers), or the dog has a myenteric plexus in the esophagus with which the vagus above the section makes contact and by which it relays impulses to the cardia.

SUMMARY AND CONCLUSIONS

By the use of balloons it was possible to make a careful study of the activity of the esophagus, cardia and stomach, without the use of an anesthetic, in dogs with gastric and esophageal fistulae. Either deglutition or a secondary peristaltic wave of the esophagus initiated by distending an esophageal balloon, is effective in inducing a relaxation of the cardia and stomach. Even though this wave may appear to die out before reaching the cardia, inhibition takes place. Reflex inhibition is always begun before the wave in the esophagus has had time to reach the cardia. This would indicate that in deglutition and in stimulating the esophagus by a balloon nerve impulses reach the cardia and elicit inhibition at once. A peristaltic wave may or may not follow. If these impulses travel by way of long vagus fibers, such fibers must be given off above the hilus of the lung. Thus nerve impulses might reach the cardia directly by long fibers in the esophageal wall or by way of cells of Auerbach.

The cardiac sphincter in the dog is not materially affected in tonus or powers of relaxation by section of the vagi in the thorax or by section of the sympathetics. No marked spasm and no paralysis was observed immediately following or months after such nerve section. Double vagotomy in the thorax followed by section of the sympathetics gave similar results. Section of one vagus trunk in the cervical region while raising the threshold for initiation of a wave in the esophagus, did not otherwise affect the relaxation of the cardia and stomach. Section of both vagi in the cervical region results in a paralyzed esophagus and an inability to elicit inhibition of the cardia. The tone of the cardia, at first, was slightly decreased by this operation but later regained, while the stomach tended to become hypertonic.

Receptive relaxation would not seem to be dependent upon the vagi alone if cutting these trunks in the thorax means that all vagus fibers to the cardia and stomach have been interrupted. The reflex is abolished when the vagi are sectioned in the cervical region but the esophagus is paralyzed by this operation. Consequently the nervous relationship between the esophagus and cardia has been destroyed.

Editorials

PERSONS WHO CANNOT WEAR DENTAL PLATES

EVERY so often one sees a woman without teeth. Ask her why she isn't wearing plates and the answer is that she has three or four sets but she cannot stand any one of them in her mouth. Perhaps she pulls two or three out of her handbag to show how bad they are and where several dentists have ground away the material in an effort to remove pressure points. If she is a woman of means, one of the pairs of plates will almost certainly be made of gold, perhaps a beautiful example of the dentist's art, but no more comfortable to wear than the others.

When one asks such a patient for more details as to why she can't wear the plates she answers that they burn her palate, or they don't seem to fit, or they gag her, or she can never forget that they are in her mouth, or they make her terribly nervous.

After one has met a number of these women one can begin to see that they fall into a type: they are all hypersensitive and fussy and nervous; everything annoys them, and they are full of aches and pains. Not infrequently one finds on questioning them that they never could brush their back teeth without getting nauseated. As one might expect, after their teeth are out they go from one dentist to another, hoping always to find some paragon who will either make a new and satisfactory plate, or will so adjust one of the old plates that it will be comfortable in the mouth. Actually, no one ever seems to be able to help them, and this is not surprising when one comes to realize that the trouble is with them and not with the plates.

Obviously the lesson each physician must learn

Preliminary Program of Annual Meeting of the American Gastro-Enterological Association

MONDAY, JUNE 7, 1937

MORNING SESSION, 9:00 A. M.
(Daylight Saving Time)

MEMORIAL ADDRESSES
of
Dr. Henry Plummer, Dr. Sidney Simon, Dr. Frank Smithies

PRESIDENTIAL ADDRESS
Dr. Chester M. Jones, Boston, Mass.

1. "The Influence of the Extrinsic Innervation on the Human Gastric Motor Mechanism"
   Dr. Louis E. Barron (by invitation) Columbus, Ohio

2. "Experimental Studies in Gastric Physiology in Man"
   V. Influence of Osmotic Tension in the Duodenum on Pyloric Action and Gastric Evacuation
   Dr. J. Gershon-Cohen (by invitation) Philadelphia, Pa.
   Dr. Harry Shay, Philadelphia, Pa.

3. "A Theory on the Formation of Peptic Ulcer"
   Dr. Heinrich Necheles, Chicago, Illinois

4. "Massive Gastric Hemorrhage"
   Dr. John M. Blackford, Seattle, Wash.

5. "Hemorrhagic Gastritis: A Gastroscopic Study"
   Dr. Edward B. Benedict (by invitation) Boston, Mass.

THE ALVAREZ LECTURE
(Founded in 1929 by Dr. Frank Smithies)
Dr. Raoul Bensaude of Paris, has been invited to deliver the Alvarez Lecture

Adjournment for Luncheon

2:30 P. M.

6. "Cinefluorographic Studies of Lesions of the Gastro-Intestinal Tract"
   Dr. Dewitt Stetten, New York, N. Y.
   Dr. William H. Stewart, New York, N. Y.

7. "Observations on Gastric Acidity Before and After Development of Gastric Carcinoma"
   Dr. Mandred W. Comfort, Rochester, Minn.

    Dr. J. Arnold Bargen, Rochester, Minn.
    Dr. Jesse L. Bollman (by invitation) Rochester, Minn.
    Dr. Edwin J. Kepler (by invitation) Rochester, Minn.

15. "The Diagnosis and Treatment of Acute Non-*Hemorrhagic Pancreatitis*"
    Dr. Robert Elman, St. Louis, Mo.

Adjournment for Luncheon

fact this is indicated by the work of Harrison and McSwiney (8).

Gastric juice of nervous or central origin is rich in both acid and pepsin. If this type of secretion is actually mediated by acetylcholine, then the latter drug, or one of its derivatives, might be of value in testing clinically for achlorhydria and achylia, and might possess an important advantage over histamine in that the reactivity of the pepsin-secreting cells might also be determined (9). It would also be of academic interest and possibly in the future of practical value to know whether or not histamine and acetylcholine act upon the same receptive mechanism in the parietal cells.

Book Reviews

Dietetics for the Clinician. By Milton A. Bridges, B.S., M.D., F.A.C.P. Oct., 1055 pages. Third Revised Edition. Lea & Febiger, Philadelphia. $10.00.

PREPARED with skill and obvious painstaking effort of unusual degree, and with the help of several co-authors, this volume begins with a description of the mechanics of digestion and a review of the physiology and chemistry of digestion. The vitamin factors in diet are fully described, and due allowance is made for *undiscovered* vitamins: owing to the certain presence of these latter in food, it is better to insure vitamin adequacy by prescribing foods rather than to rely solely upon special vitamin concentrates. A long chapter on the classification and structure of foods shows the sources of, requirement in, and opportunities for deficiency in, carbohydrates, fats, proteins, purins, cholesterol, minerals, water and vitamins. An extremely practical chapter on the evaluation of foods, shows the effects of cooking; the availability of food elements; and especially the therapeutic effects of food, as for example—gravies, and over-ingestion of water in the production or aggravation of gastric hypersecretion. Food adjuncts—alcohol, tea, coffee, condiments and spices—receive interesting consideration and even the effects of tobacco on diet is described. Various methods of feeding—by catheter, duodenal tube and rectal tube are detailed with suitable food prescriptions in each case. About one-half of the book is devoted to the dietetic management of diseases of adults, and this is followed by a smaller section on infant feeding and diseases of childhood. An extremely extensive "appendix" contains height and weight tables, caloric value of foods, composition of various foods and beverages, practical recipes, and bibliographies on many special topics. Finally, a general bibliography and a complete index completes a volume which, because of its reference value, deserves a place in the library of every practising physician.

Beaumont S. Cornell, Fort Wayne, Ind.

Cancer and Diet. By Frederick L. Hoffman, L.L.D. The Williams and Wilkins Company, Baltimore, Md., 1937, pp. 767, $5.00.

THE section on dietary theories of cancer etiology, while interesting, is, of necessity, confusing. The shorter section on the modern diet is intrinsically valuable, quite apart from any possible bearing on cancer. The long section on cancer metabolism will be welcomed by many readers for its convenient reference value. The balance of the book concerns an original dietary enquiry into the food habits of over 3000 cancer cases, statistically tabulated in contrast with a suitable number of non-cancer controls. The results scarcely support the author's belief that over-nutrition plays an important role in cancer etiology.

There is a growing tendency to side-step the problem of the cause of cancer by regarding the malignant process as a "mutation" utterly impregnable by all methods of investigation. Hoffman's laborious study is a refreshing antithesis to such reactionary attitude and is admirable in many points. It is unfortunate that he occasionally refers to authorities who are more or less discredited. It is unfortunate that the "dietary enquiry" method is open to so many inaccuracies. But fortunate indeed would be a world peopled with men of Hoffman's intellectual aspiration and industry.

Beaumont S. Cornell, Fort Wayne, Indiana.

CREAM OF WHEAT

When Diet Itself

Becomes a Therapeutic Factor

ACCEPTED AMERICAN MEDICAL ASSN. Council on Foods

In many affections of the gastro-intestinal tract, and during the course of numerous infectious diseases, diet often assumes equal importance with specific therapy. In such cases, Cream of Wheat is especially valuable. When cooked, it consists of soft, non-irritating wheat granules which are mechanically bland and evoke a minimum flow of acid gastric juice. Furthermore, Cream of Wheat is high in nutritional value, an ounce yielding 115 calories of quickly assimilated food energy.

Because of these physical and chemical properties, Cream of Wheat finds an important place in the dietaries of patients afflicted with peptic ulcer, the various dysenteries, colitis, and as a rapidly available source of energy in infectious diseases and convalescence.

ROSENBERG, DAVID H., WITH THE TECHNICAL ASSISTANCE OF WALTERS, A.

Macrocytic Anemia in Liver Disease, Particularly Cirrhosis. Observations on the incidence, course and reticulocytosis with a correlated study of the gastric acidity. Am. Jour. Med. Sci., July, 1936.

Of forty-eight patients with hepatic cirrhosis, a macrocytosis was found in 43 instances, an incidence 89.7%. It was also found in seven cases of acute toxic hepatitis, in three cases of obstructive jaundice, due to pancreatic carcinoma with extensive metastasis to the liver. In acute yellow atrophy of the liver macrocytosis was present with a normal erythrocyte count and a subnormal mean corpuscular hemoglobin concentration. A reticulocytosis varying from 1.1 to 18.0% and averaging 2.47% was found in 39 out of 62 patients. This would indicate an active erythropoiesis. The highest percentages were noted in three of the patients with the more advanced anemia. In 43 patients with icterus, 30 showed reticulocytosis, whereas in only 9 out of 19 individuals without icterus was reticulocytosis found. Achlorhydria co-existing with a macrocytic anemia may denote a deficiency of the intrinsic factor of Castle. In only 11 of 48 patients examined for their gastric acidity was a true achlorhydria found. No relationship was found between achlorhydria and macrocytic anemia in liver disease. The view of a deficient storage or utilization of the active hematopoietic principle by a defective liver seems at present to be the most tenable explanation of the macrocytic anemias in liver disease.

In summary, the authors say that in various forms of widespread or advanced hepatic disease, either a macrocytic anemia or macrocytosis alone was found in 91% of the patients. A reticulocytosis occurred in 39 patients and was more common with bilirubinemia. Macrocytosis in liver disease may possibly result from a primary swelling of the erythrocytes followed by the secondary appearance of true macrocytes.

Allen Jones, Buffalo.

WARTHEN, HARRY J. AND GRIFFIN, V. H.

"Simple Cyst of the Liver: Report of a Case." South. Med. Jour., 29:1178-1180, Dec., 1936.

Simple cysts of the liver are quite rare. Frequently the etiology, as in the case reported, can not be demonstrated but in others the lining membrane will suggest biliary or lymphatic origin. Total excision is the treatment of choice but often evacuation and marsupialization are all that can be done. In the case reported the patient was a negress 38 years of age. The illness began 9 months previous to operation with an upper respiratory infection, pain in the lower right chest, cough but no sputum, and a questionable fever. One week later the abdomen began to enlarge and within another week reached its maximum size. There was no nausea, vomiting or abdominal pain, but there was extreme weakness and during the entire 9 months an amenorrhea. Abdominal examination showed a smooth cystic mass extending from the costal margin to the pelvis. There was dullness to percussion but no fluid wave, tenderness or rigidity. Vaginal examination showed fullness in the right fornix, the cervix smooth and the fundus displaced to the left. There was marked secondary anemia and a positive blood Wassermann test. The cyst was evacuated and excised. No pedicle was found but there were numerous adhesions to the stomach and coils of intestines. An uneventful recovery occurred.

J. Duffy Hancock, Louisville.

SHERWOOD, T. C.

Relation of Season, Sex and Weight to the Basal Metabolism of the Albino Rat. Jour. Nutrit., 12, 223, 1936.

Sherwood describes variations in the basal metabolism of the Albino rat not dependent upon the seasons, body weight, sex and the sexual activity. The availability of calcium and iron in spinach is only partial according to Horwitt, Cowgill and Mendel. Three articles upon vitamin metabolism emphasize the loss of vitamin C in the cooking water in the case of Peas (Fenton, Tressler and King). When vitamin G which is obtained in alfalfa leaf meal and dried skim milk and etcetera, is included in the hen's diet there is an improvement in the hatchability of eggs which is an important fact in human dietetics because the ration of the hen directly affects the vitamin G content of the eggs produced.

Howard Frank Root, Boston.

RABINOWITCH, I. M. AND SMITH, F. C.

Metabolic Studies of Eskimos in the Canadian Eastern Arctic. Jour. Nutrit., Vol. 12, 337, Oct. 10, 1936.

The metabolic studies of Eskimos reported by Rabinowitch were carried out during the Canadian Government Eastern Arctic Patrol on the R.M.S. Nascopie. High values for non-protein nitrogen, urea nitrogen and amino-acid nitrogen occurred among the 46 cases studied, and are explained as due to the enormous quantities of meat eaten, often in a putrified state. When food is plentiful, a healthy adult may eat 5 pounds or more a day. High plasma chloride values contrasted with low con-

centrations of chloride in the urine, the latter dependent chiefly upon the absence of sodium chloride in the diet except as it naturally occurs in meat.

Polycythemia occurred in a number of Eskimos, and copper excretion in the urine was measured with the hope that some light would be thrown upon the relation of copper to hemoglobin formation. The concentration of copper was on the average four times as high in the urine of Eskimos living on the natural diet high in meat, as among Eskimos living on a diet including an appreciable amount of civilized man's food.

Glycosuria and Ketonuria were not found. The diet of the adult Eskimo in Canadian Eastern Arctic was found to contain approximately carbohydrate 40 grams, protein 250 to 300 grams and about 150 grams fat. The use of "banik," a mixture of water, baking soda and flour, especially when finances permit, tends toward a condition of alkalosis rather than the Ketosis which might be expected from the high fat diet with the absence of sodium chloride.

Blood sugar curves, performed after the ingestion of 50 grams of glucose in 13 cases showed high values (Myers-Benedict picric acid method). The average value after 30 minutes was 0.21 per cent (210 milligrams). Only six urine specimens showed traces of sugar, indicating a raised renal threshold for sugar.

The respiratory quotients were from 0.66 to 0.70 in six of ten cases, consistent with fat-protein diets. The average basal metabolism was plus 26 per cent.

No lead was found in the urine. The alleged absence of arteriosclerosis in Eskimos is denied and, therefore, other causes than lead poisoning must be found for its existence in the Eskimos.

Howard Frank Root, Boston.

CAMPBELL, W. R., FLETCHER, A. A. AND KERR, R. B.

Protamine Insulin in the Treatment of Diabetes Mellitus. Am. Jour. Med. Sci., Vol. 192, No. 5, Nov., 1936.

The authors give a summary of their experience in treating fifty cases of diabetes with Protamine Insulin. They point out that the severe diabetic, even with five doses of insulin a day, is subject to wide fluctuations from hypoglycemia to hyperglycemia especially during sleep. Protamine Insulin is absorbed slowly at the p.H. of the body tissues and depresses the blood sugar twice as long and with remarkably infrequent reactions. A case having a reaction at noon after twenty units of regular insulin before breakfast in the morning was able to take fifty units of Protamine Insulin without reaction and without any undue lowering of the blood sugar. Small increases in the dose of Protamine Insulin prolong the action without increasing the rate of fall of blood sugar. This slow fall apparently enables the patient to tolerate a blood sugar of 45 without hypoglycemic symptoms. An early morning injection of Protamine Insulin causes the lowest blood sugar reading about twelve midnight to 4:00 A. M. or about eighteen to twenty-four hours later. Accordingly, carbohydrate food is recommended in the evening or at least a shift from breakfast to the evening meal. When reactions do occur they may extend over a longer period than with regular insulin and several portions of orange juice or of bread or rice or other starchy foods may be necessary. No local reactions were observed since Protamine presumably is non-antigenic in nature.

The authors give the technique as follows:

To change from a regimen of regular insulin to Protamine Insulin 75% to 100% of the old dosage is given as a single morning injection of Protamine Insulin and for the first day 60% of regular insulin in two doses, one morning and one evening. For the second day 30% of the old dose of regular insulin in the morning and later only the Protamine Insulin each morning. The initial treatment in a new case may be carried out in the same way. Some cases will require a supplement of regular insulin and considerable individualization is necessary. There seems to be some variation in the rate of absorption of Protamine Insulin, some requiring an additional bed-time dose and others requiring a morning injection of regular insulin.

It is desirable to prevent postprandial hyperglycemia as far as possible. The amount of free insulin (now 4%) in Protamine Insulin might be varied. Protamine Insulin may be taken one to three hours before meals. The authors seem to prefer a relatively low carbohydrate diet. Overlapping of the second dose of Protamine Insulin some ten hours after the first dose helps to meet the postprandial rise. In some cases, too, the regular insulin in the morning, and the evening dose of Protamine Insulin maintains a blood sugar at the lowest constant level and in this way provides the greatest degree of functional rest to the pancreas. With regular insulin, especially in its purest form, three-fifths of the day there is no functional support of the pancreas and hence no aid in building up a carbohydrate tolerance.

For all these reasons the authors conclude that Protamine Insulin is a real contribution and will be a simpler and more economical as well as more effective form of treatment.

V. C. Rowland, Cleveland.

CASTLE, W. B. AND HAM, THOMAS HALE.

Observations on the Etiologic Relationship of Achylia Gastrica to Pernicious Anemia. J. A. M. A., Vol. 107, pp. 1456-1463, Oct. 31, 1936.

Patients with pernicious anemia appear to be unable to derive from food some substance essential for the normal function of the bone marrow. The cause of this seems to be the failure of a reaction between a substance in the food (extrinsic factor) and a substance in the normal gastric secretion (intrinsic factor). This conclusion is based on the following facts:

1. The daily administration of (extrinsic factor) 200 grams of beef muscle is without significant effect on blood formation.

2. The daily administration of (intrinsic factor) from 150 to 300 c.c. of normal human gastric juice is without significant effect on blood formation.

3. If, however, such amounts of each substance are administered daily in such a way as to permit contact either before or after administration, chemical improvement and evidence of increased blood formation are apparent within ten days and are progressive for the duration of such therapy.

In a recent paper, Greenspon has presented the results of experiments from which he has drawn the conclusion that an extrinsic or food factor is unessential to the production of the positive effects on blood formation in pernicious anemia. He believes that the authors' negative results with normal human gastric juice alone were due to destruction of an "antipernicious anemia principle" by peptic action during the course of preliminary incubation. In the authors' former experiments gastric juice which was not incubated before administration yielded negative results. Nevertheless the inactivity of such gastric juice, according to Greenspon, was due to peptic hydralysis in viva after administration to the patient.

The ten patients included in the present observations were all typical cases of addisonian pernicious anemia. The negative and positive effect on blood formation was determined by the reticulocyte response. The gastric juice used was from an apparently normal person and was collected after the injection of 0.5 mg. of histamine and then filtered through a coarse cloth and placed in the icebox. The patients were on a diet which contained no meat, eggs, liver or kidney. Chicken and fish were allowed once or twice a week. In six cases during the period of observation the diet was further restricted to white bread, rice, macarone, butter, potato, ice cream, tea, coffee and sugar.

The observations made were:

"Normal human gastric juice does not contain an 'antipernicious anemia principle' effective on oral administra-

tion without contact with food factor."

The technic used by Greenspon was followed except that no ice was put in the gastric juice and the time interval was lengthened to six hours. No reticulocyte or red blood cell response was noted in any of the cases. On the other hand these same patients all responded well to the administration of beef muscle and gastric juice or boiled hog mucosa and gastric juice when given simultaneously or when given ventriculin. Greenspon's result may have been due to the fact that he only excluded liver and kidney from the diet. In addition, the time interval between the giving of the gastric juice and the next meal (four hours) may not have been sufficient to prevent effective contact between the gastric juice and the food. This may be shown by the patient who was given 200 grams of beef muscle followed in six hours by 100 c.c. of gastric juice and who showed a reticulocyte response and clinical improvement. Furthermore, since the gastric juice used in this particular experiment produced positive results in conjunction with beef muscle the precautions advocated by Greenspon to prevent peptic activity are not essential to the preservation of the intrinsic factor.

"The activity of desiccated hog stomach mucosa is due to the presence of both intrinsic and extrinsic factors." This was shown by the fact that no response occurred when the intrinsic factor of hog stomach mucosa was destroyed, while the same patient responded to the oral administration of liver extract — Lilly. In addition to this, to show that extrinsic factor is present in hog stomach mucosa, the intrinsic factor was destroyed and the remainder with gastric juice fed to patients. This was followed by a reticulocyte response and clinical improvement.

It was also shown that a two hour period of incubation of gastric juice in a medium favorable for peptic hydrolysis was detrimental to the intrinsic factor, thus sustaining one of Greenspon's beliefs.

"Beef muscle and gastric juice administered without opportunity for contact are wholly ineffective." This was ascertained by feeding beef muscle and gastric juice twelve hours apart. In these cases there was no reticulocyte response until the two substances were given simultaneously.

"Former experiments apparently demonstrating the absence of extrinsic factor from certain substances are not necessarily valid." This in agreement with Greenspon is apparently due to the action of native pepsin and hydrochloric acid which results in peptic hydrolysis. However, Castle suggests that it may not be the hydrolysis but the temperature which brings about this destruction.

Francis D. Murphy, Milwaukee.

Nutritive and Therapeutic Value of the Banana (a digest of scientific literature).

The research department of the United Fruit Company who in the past have been frequently responsible for many interesting and useful additions to medical knowledge, have taken the time to produce for medical study an attractive 150 page book, in which all medical and botanical references of importance to bananas during the past few years are carefully gathered together. Just as the tomato ("love apple") was regarded as poisonous and honored only for its decorative qualities, until by slow degrees it was discovered not only to be edible, but eventually recognized as a good source of vitamins A and C, so the story of the banana reveals a long period in which, while not viewed as poisonous, it was nevertheless sternly forbidden to invalids and children. For many years indeed, we can all remember that the banana was said to be highly indigestible, and all *bona fide* lists for infant feeding had the fruit under the "don't" department. The editorial department of the Journal of the American Medical Association was among the first to come to the rescue, by showing the tremendous difference between the chemistry of the ripe and the green product. Ripening changes the high starch content to an easily absorbed carbohydrate form (soluble sugars), a process accomplished by the bananas own ferments. A ripe banana has a lot of brown in its skin but this means ripeness, not "rottenness." The inside of a banana is sterile. Bananas seldom cause allergic symptoms. The mineral content shows a very wide range of elements and the ash is alkaline. Vitamins A and C are well represented and B and G are present as well. The banana is enjoying a present vogue in many reducing diets. Its value as a food for children and adults both in health and disease deserves attention.

GUTHRIE, J. S. AND BARGEN, J. ARNOLD.

The Effects of Drugs on Different Segments of the Intestine of Man. S. G. O., Vol. 63, No. 6, pp. 743-749, Dec., 1936.

By means of air filled balloons attached to kymographs and inserted into segments of the intestine of man, the authors were able to secure graphic tracings representing the intestinal contractions resultant from the intramuscular injection of certain drugs. The drugs studied were (1) surgical pituitrin, (2) physostigmine salicylate, (3) peristaltin or a soluble extract of cascara sagrada, grains 2½ per ampul, prepared for hypodermic injection, and (4) acetylcholine. The segments of the bowel studied were the ileum, the transverse colon and the sigmoid colon.

Of the four drugs used the authors found that pituitrin alone was a marked stimulant of the human intestine. It stimulated all segments studied and did not increase intestinal tonus. It was consistent, rapid and uniformly powerful in its action. Physostigmine in doses of 1/35 to 1/50 grain, and peristaltin caused only slight intestinal contractions in certain instances. They caused some increase in the tonus of the intestines. Acetylcholine was found to possess little worth as a stimulant of the human intestine. On 7 of 9 occasions on which it was used no evidence of any effect on the intestine was in any way apparent.

Six figures and a bibliography accompany the article.

FAULEY, G. B. AND IVY, A. C.

The Prevention of Postoperative Jejunal Ulcers by Diet and Fundusectomy. An Experimental Study in Dogs. S. G. O., Vol. 63, No. 6, pp. 717-723, Dec., 1936.

In an attempt to determine the value of fundusectomy and diet in the prevention of postoperative jejunal ulcers, the authors studied four groups of dogs. The first group was composed of 11 dogs in which the Mann-Williamson operation followed by fundusectomy was performed; they were fed on stock diet. Three developed jejunal ulcers. All lost weight so rapidly that a special diet high in nuclear substances, vitamins and carbohydrates was devised to prolong their period of postoperative survival. Group two was composed of 20 dogs who had been subjected to the Mann-Williamson operation and fundusectomy. In the 10 dogs surviving more than seventeen weeks 9 developed jejunal ulcer. In group three, 13 animals were subjected to fundusectomy, and a month later the Mann-Williamson operation, after which they were fed the special diet. None of this group developed ulcer after periods of one year in seven, and two years in six. In group four the blood supply to the fundus was ligated instead of the fundusectomy as was performed in the other groups. This procedure was not nearly as effective as fundusectomy in preventing jejunal ulcers.

From this study the authors conclude that fundusectomy and the special diet have definite value in the prevention of postoperative jejunal ulcers.

Four figures and five tables accompany the article.

Nelson M. Percy, Chicago.

The following list of abstracts throw light on the vitamin value of canned foods:*

HANNING, FLORA.

Canned Strained Vegetables as Sources of Vitamin A. 1933, J. Am. Dict. Assoc., 9, 295.

The author reported the number of milligrams of certain commercially prepared strained foods required to supply one Sherman unit of Vitamin A. Using these data the abstractor has calculated the units per gram and per ounce:

Strained Product	Sherman Units of Vitamin A Per Gram	Per Ounce
Spinach	66	1870
Carrots	25	710
Tomato	20	560
Peas	6.6	187
Green beans	4	113
Vegetable soup	6.6	187

Canned strained spinach, carrots and tomatoes were found to be excellent sources of vitamin A. Canned strained green beans, peas and vegetable soup were shown to be good sources of the vitamin. On the basis of food solids the strained canned foods were approximately equal to the raw foods as sources of vitamin A.

EDDY, WALTER H., KOHMAN, E. F. AND HALLIDAY, NELLIE.

Vitamins in Canned Food. VII. Effect of Storage on Vitamin Values of Canned Spinach. 1929, Ind. Eng. Chem., 21, 347.

A two year storage period had little effect on the vitamin C content of spinach, 4 grams affording protection at both the beginning and end of that period, although there was a slightly less growth promoting effect in the case of the stored product.

Canned spinach showed no detectable loss of vitamin A after two years' storage, 26 mg. daily permitting an average of 52 grams gain in 60 days.

1930, Michigan State Agr. Expt. Sta. Bien, Rpt., pp. 36.

Commercially canned white Country Gentleman corn fed in 7 gram amounts failed to prevent loss of weight in rats on test for vitamin A, thus indicating the presence of only a trace of the vitamin. Commercially canned yellow Golden Bantam corn, on the other hand, showed a high vitamin A content.

The yellow corn is also richer in undifferentiated vitamin B, 5 to 6 grams containing one Sherman unit; while 8 to 9 grams of white corn are required to furnish this amount.

MILLER, CAREY D.

Vitamins A and B in Fresh and Canned Pineapple. 1924, J. Home Econ., 16, 18.

Commercially canned pineapple, while slightly inferior to the fresh product in vitamin A, may be regarded as a good source of this dietary factor.

The effect of the canning process on the vitamin B content of pineapple cannot be great, as the growth curves from the canned product were only slightly inferior to those of the fresh. Both are considered good sources of vitamin B.

Rated in terms of the plus and minus signs initiated by the British Research Committee and widely used by others, the content of fresh and canned pineapple in vitamins A and B would each be indicated by the two plus signs.

HANNING, FLORA.

Further Studies of the Content of Vitamin B in Canned Strained Vegetables. 1936, J. Am. Diet. Assn., 12, 231.

Vitamin A in commercially canned strained vegetables was determined by the Sherman and Munsell assay method. The following results are expressed in International Units per gram.

Year Packed	1930-1931	1932	1933
Spinach	118	127	118
Carrots	61	63	66
Tomatoes	43	47	39
Peas	8	10	12
Green Beans	8	7	12

The Chase and Sherman method was used in the vitamin B assays with the

A Clinically Effective Detoxifying Agent

MORRIS AND DORST REPORT THAT—"Sodium ricinoleate detoxifies many organisms in the enteric flora in vitro." . . . and "there is worthy evidence to suggest that sodium ricinoleate administered by mouth exerts a detoxifying action in the enteric flora in vivo."

BURGER STATES—"It is felt that soricin is of definite benefit in the treatment of irritable colon. . . . There is a decrease in the skin sensitivity to bacterial vaccines following treatment with soricin."

JACKSON WRITES—"I have been employing sodium ricinoleate as an intestinal detoxifying agent with most gratifying results. . . . At the moment we know of no detoxifying agent which acts so rapidly and efficiently as sodium ricinoleate."

KLINE OBSERVES—"That it (Soricin) appears to maintain the normal intestinal gradient and to reduce toxemia; and that it shows evidence of relieving the symptoms attendant upon intestinal tuberculosis without the necessity of producing purgation."

Soricin

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes.
Soricin Tablets—Enteric coated tablets each containing five grains of sodium ricinoleate.
Soricin and Bile Salts Tablets—Enteric coated tablets, each containing four and one-half grains of sodium ricinoleate, and one-half grain of bile salts.

ACTION: Detoxifies in vivo • Desensitizes • Inhibits putrefaction • Prevents toxic absorption.

INDICATIONS: Bacterial Hypersensitivity of the intestinal tract • Intestinal toxemia • Intestinal allergy • Allergic diarrhea • Urticaria—angioneurotic edema • Colitis.

Literature and Sample on Request

THE WM. S. MERRELL COMPANY, Cincinnati, U. S. A.

following results, also expressed in International Units per gram.

Year Packed	1932	1934
Tomatoes	0.42	0.25
Peas	0.12	0.29
Green Beans	0.08	0.11
Carrots	0.08	0.11
Beets	0.06	0.04
Spinach	0.05	0.06

Canned strained spinach, carrots and tomatoes were found to be good sources of vitamin A; peas and green beans also containing significant amounts. Little variation was found between different year's packs.

The vitamin B content of tomatoes and peas was found to be high and green beans, carrots, beets and spinach are valuable sources of the vitamin.

MOORE, MARGARET C. AND MOSELEY, HAL W.

A Study of Canned Shrimp with Reference to the Presence of Vitamins A, B and D. 1933, Science, 78, 368.

Vitamins A and D were shown to be present in about equal amounts in both wet-pack and dry-pack canned shrimp fat.

The animals receiving the vitamin A-free diet supplemented with 0.2-0.3 grams of shrimp fat daily grew as well as the young stock colony animals.

The animals which received 10-15 grams of the canned shrimp (0.2-0.3 grams fatty extract) daily for 13 days after their vitamin D depletion period were either entirely cured or showed marked improvement in the rachitic condition.

Vitamin B is either absent, or present in very small quantities.

HANNING, FLORA.

A Comparison of Vitamins B and G in Canned Strained Foods. 1934, J. Nutrition, 8, 449.

The samples of strained foods examined were representative of the 1931 or 1932 packs of a well known brand. The results of the studies are reported in Sherman units per ounce.

Canned Strained Food	Units of Vitamin B per Ounce	Units of Vitamin G per Ounce
Beets	3.3	3.3
Carrots	4.3	2.5
Cereal	7.5	12.0
Green Beans	4.7	6.0
Peas	7.0-8.0	7.5-8.6
Spinach	2.5	7.5-11.8
Tomato	20-24	6.7
Vegetable Soup	3.0	3.0

Of the foods examined the most potent sources of vitamin B are tomato, peas, and cereal; and the best sources of vitamin G are cereal, spinach and peas.

KOHMAN, E. F., EDDY, W. H. AND HALLIDAY, NELLIE.

Vitamins in Canned Food. VI. Strawberries. 1928, Ind. Eng. Chem., 20, 202.

Commercially canned strawberries after a year's storage were found to have a vitamin C content similar to that of fresh strawberries, which in turn are comparable to tomatoes in their content of this essential food factor. Consequently, canned strawberries can be regarded as a rich source of the antiscorbutic factor.

Strawberries are relatively low in vitamin A, being about one-fortieth as potent as tomatoes. The vitamin B content is higher, however, being about one-fourth that of tomatoes.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

mercially canned spinach is an excellent source of vitamin A. Twenty-six milligrams of canned, raw, or home cooked spinach per day meet the vitamin A requirement of the rat and produce almost normal growth. Vitamin A in spinach is not appreciably affected by canning or cooking.

Daily doses of 4.0 grams of canned spinach or 1.0 gram of raw spinach protected guinea pigs from scurvy. Home cooked spinach was not protective in daily allowances of 10.0 grams. These findings demonstrate that the vitamin C content of spinach as consumed is dependent upon the method of preparation. Commercially canned spinach has far greater antiscorbutic potency than fresh spinach cooked in an open kettle.

TODHUNTER, E. N.

A Comparison of the Vitamin G Values of Pasteurized Milk, Evaporated Milk and Eggs. 1932, J. Am. Dietetic Assoc., 8, 42.

The vitamin G content of evaporated milk (a composite of five brands available in the open market) was compared with that of pasteurized market milk by means of the Bourquin and Sherman method. Supplements of 12 ml. and 24 ml. per week of evaporated milk diluted (1:1) produced average gains of 28.5 grams and 54.1 grams respectively, as compared to gains of 30.9 grams and 52.8 grams in eight weeks produced by equal quantities of pasteurized market milk.

The author calculates that 10.1 ml. per week of diluted evaporated milk or 9.3 ml. per week of pasteurized milk produces unit growth. Expressing these values in terms of Sherman units of vitamin G per pound and per gram:

Product	Sherman Units of Vitamin G Per Pound	Per Gram
Evaporated milk diluted as per instructions on container (1:1)	300	0.66
Pasteurized milk	335	0.74

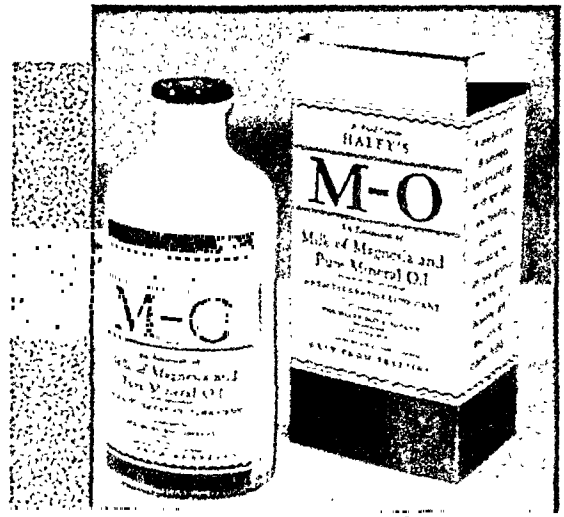
The author concluded that the vitamin G content of evaporated milk diluted (1:1) is substantially like that of pasteurized market milk.

KOHMAN, E. F., EDDY, W. H. AND GUBIN, CELIA ZALL.

Vitamins in Canned Foods. X. The Vitamin Content of Some Common Vegetables. 1931, Ind. Eng. Chem., 23, 808.

Canned turnip greens are outstandingly rich in vitamin A, being unsurpassed by any other vegetable and comparable to spinach in this respect. Twenty-five milligrams were equivalent to 5 grams of bleached or 500 mg. of unbleached celery. Canned turnip greens are not a potent source of vitamin B_1, but are a fair source of vitamin B_2 (G).

Canned turnip greens in 2-4 gram dosages proved more potent in vitamin C than 5 grams of celery, green or bleached, 10 to 15 grams of head lettuce, inner or outer leaves, or 10 grams of whole or 15 grams of shredded carrots.



POE, C. F. AND CAMBELL, E. L.

Vitamin G Content of Commercially Canned Tomato Juice. 1933, J. Am. Dict. Assoc., 11, 343.

A modification of the Bourquin and Sherman method was used in determining the vitamin G content of some representative brands of commercially canned tomato juice. The rats were fed doses ranging from 2 ml. to 12 ml. per day.

No animals receiving 4 ml. or more of juice developed dermatitis or other symptoms of vitamin G deficiency. The vitamin G values of the 18 samples examined ranged from 0.18 to 0.28 Sherman units per ml. with an average of 0.21 units per ml. Commercially canned tomato juice contains an average

Samples to Physicians on Request

The Chas. H. Phillips Chemical Co.
170 Varick Street New York, N.Y.

of approximately 100 Sherman units of vitamin G per pound.

Filtered tomato juice from 4 samples of commercially canned whole juice was found to have essentially the same vitamin G content as the juice from which it was prepared.

EDDY, W. H., KOHMAN, E. F. AND CARLSSON, VICTORIA.

Vitamins in Canned Foods. IV. Green Peas. 1926, Ind. Eng. Chem., 18, 85.

Commercially canned peas are one-sixth to one-half as rich in vitamin A as butter, being closer to the latter than former value. Young peas contain more of this vitamin than the more mature ones.

The vitamin B-complex requirement for growth of the rat was met by a daily dose of 5 grams of canned peas. Larger and more mature peas contain more vitamin B-complex than smaller less mature ones.

Canned peas were shown to retain at least one-half to two-thirds of the vitamin C of raw peas. Reheating canned peas before serving did not seriously affect their antiscorbutic properties.

Commercially canned peas are an excellent source of vitamin A and a valuable source of vitamins B-complex and C in the diet.

EDDY, W. H., GURIN, CELIA ZALL AND KOHMAN, E. F.

Vitamins in Canned Foods. XII. Supplementary Nature of Grapefruit and Prunes. 1932, Ind. Eng. Chem., 24, 457.

Commercially canned prunes (Italian or French) proved to be rich in vitamin A. This product can not be considered a rich source of vitamin C. Canned prunes were approximately equivalent to milk in vitamins B and G. As in the case of milk, they contained somewhat more vitamin G than B.

The vitamin A content of canned prunes compared favorably with that of the fresh fruit. The canned product contains a smaller amount of the antiscorbutic factor than the fresh fruit.

FELLERS, CARL R.

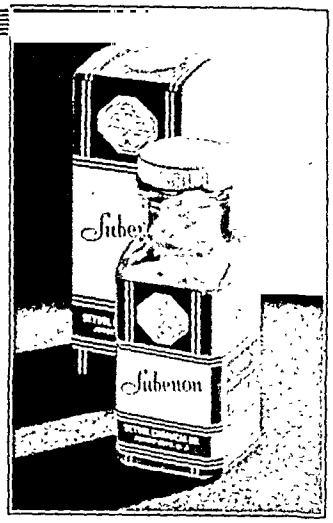
Vitamin Content of Important Foods in the Child's Diet. 1935, Am. J. Pub. Health, 25, 1340.

Normal fresh milk and reconstituted canned milk have a small and relatively constant vitamin D content of 20 to 27 U.S.P. units per quart. The vitamin D value of milk is not altered by the processes of pasteurization, homogenization, or canning.

Two samples of irradiated canned milk were found to contain 270 U.S.P. units of vitamin D per quart, thus the reconstituted milk would contain 135 units per quart. Clinical data indicate that canned irradiated milk supplies sufficient vitamin D to prevent rickets in normal infants.

The vitamin A potency of milk is not impaired by manufacturing processes such as pasteurization, homogenization, or canning.

The vitamin A and vitamin D potencies of irradiated canned milk are of relatively much greater importance than those of vitamins B, C and G, which are also present in this product.



KOHMAN, E. F., EDDY, W. H. AND GURIN, CELIA ZALL.

Vitamins in Canned Foods. IX. Tomato Products. 1930, Ind. Eng. Chem., 22, 1015.

The vitamin A content of tomatoes and tomato products is practically unaffected by the commercial canning procedure, while the vitamin B content may be somewhat affected.

Vitamin C in tomatoes and tomato products is quite stable to heat, if oxidation is avoided. Any preliminary process which introduces air will result in destruction of vitamin C in proportion to the degree of exposure and the tem-

The Logical Method of Attack on Arthritis

SUBENON

SEYDEL CHEMICAL CO.
135 HALLADAY ST. JERSEY CITY, N.J.

perature to which the product is heated. The mechanics of the canning procedure provide for exclusion of oxygen with subsequent retention of vitamin C in good degree.

SAMUELS, LEO T. AND KOCH, FRED C.

The Relative Quantities of Heat-Stable and Heat-Labile Fractions of Vitamin B in Raw and Evaporated Milk.. 1932, J. Nutrition, 5, 307.

The vitamin content of commercially evaporated milk was compared with that of the frozen raw milk from which it had been made and with certified milk purchased on the open market. The frozen and certified milks had very similar antineuritic vitamin contents. The evaporated milk was found to have an antineuritic vitamin value similar to an evaporated milk composed of a mixture of two brands sold under producers' labels and two brands sold under distributors' labels.

The antineuritic vitamin content of 25 ml. of frozen raw milk was approximately the same as that of 30 ml. of milk formed by diluting (1:1) the evaporated milk to its original volume. About four-fifths to five-sixths of the antineuritic vitamin in fresh raw milk survived the processes of evaporating and canning. The heat-stable vitamin G contents of the frozen and evaporated milk were found to be practically identical.

KRAMER, MARTHA M., EDDY, WALTER H. AND KOHMAN, E. F.

Vitamins in Canned Foods. VIII. Home Canning and Commercial Canning Contrasted in their effect on Vitamin Values of Pears. 1929, Ind. Eng. Chem., 21, 859.

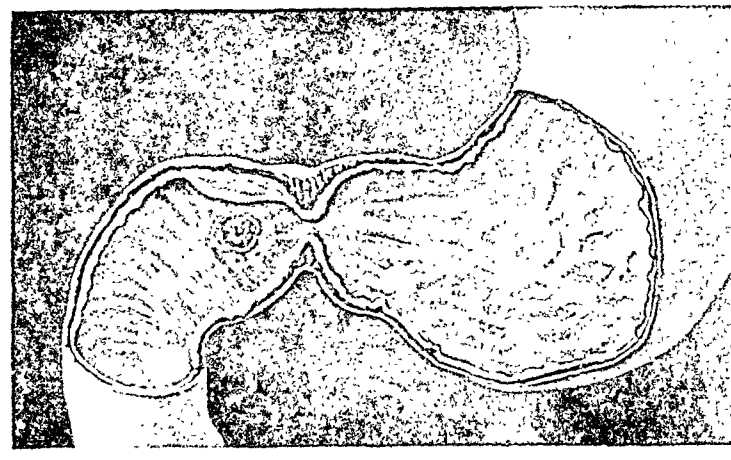
Pears were commercially canned with little loss of vitamin C, provided proper precautions were taken to prevent oxidation. When subjected to open-kettle and cold-pack methods of home canning, the vitamin C content of the pears was almost completely destroyed. When commercially canned without care to prevent oxidation 66 to 75 per cent of the antiscorbutic potency was retained. The absolute vitamin C value was not determined but it is thought to approximate that of apples.

The vitamin C potency of the canned product and the raw fruit from which it is prepared is apparently greatly affected by the degree of ripeness of the pears; the antiscorbutic value decreasing as the ripening process advances.

Raw or canned pears are relatively low in vitamins A and B.

KOHMAN, E. F., EDDY, W. H., CARLSSON AND HALLIDAY, NELLIE.

Vitamins in Canned Foods. V. Peaches. 1926, Ind. Eng. Chem., 18, 302.



Peaches canned after removal of oxygen were found to prevent scurvy when fed in daily doses of 5 grams. Some evidence of scurvy was found in guinea pigs fed 5 grams daily of peaches canned without removal of oxygen. Commercially canned peaches as a source of vitamin C are approximately equal to raw peaches purchased on the New York market, and are far superior to peaches cooked in an open kettle. Canned peaches may be considered as a good source of the antiscorbutic vitamin.

Commercially canned peaches were found to be a good source of vitamin A. On a dry basis they are one-third to one-half as rich as butter in vitamin A. The vitamin B content of peaches was found to be negligible.

DIET-ALKALI *versus* LAROSTIDIN

The Sippy treatment, in its various modifications, is so restrictive as to be irksome to many ulcer patients. They find life a sorry burden.

Larostidin is a useful adjuvant to other treatments. When Larostidin is included there is likely to be a minimum of restriction. The diet may be rapidly increased to normal, there is no interference with the patient's business or social duties, and there is frequently a remarkable uplift of the spirit that has been smothered by the chronic infirmity.

Patients who resist a certain line of treatment often respond to a new line of attack. For example, it has been demonstrated* that 70% of the diet-alkali failures make a favorable response to Larostidin.

GUERRANT, N. B., DUTCHER, R. ADAMS, TABOR, FLORENCE S. AND RASMUSSEN, RUSSEL A.

The Vitamin Content of Canned Pineapple Juice. 1936, J. Nutrition, 11, 383.

By formal biological assay, a commercially canned pineapple juice was found to have the following vitamin values:

Vitamin A: 1 Sherman unit per 1 ml., equivalent to 30 units per ounce.

Vitamin B: 1 Sherman unit per 1.5 ml., equivalent to 20 units per ounce.

Vitamin G: 1 Sherman unit per 12 ml., equivalent to 2.5 units per ounce.

Vitamin C: 1 International unit per 0.7 ml., equivalent to 40 units per ounce.

In summary it may be said that pineapple juice is a good source of vitamins A and B, a fair source of vitamin C, and contains a small but definite quantity of vitamin G.

FELLERS, C. R., CLAGUE, J. A. AND ISHAM, P. D.

Value of Commercially Canned and Laboratory - Prepared Tomato Juices as Antiscorbutics. 1935, J. Home Econ., 27, 447.

Seven lots representing four leading brands of commercially canned tomato juice were purchased at local groceries. These tomato juices were assayed for vitamin C potency by means of the Sherman LeMer and Campbell technique.

Four samples were fully protective in daily allowances of 4 grams, and all but one sample gave complete protection from scurvy at the 6 gram level. The brand of tomato juice which failed to protect guinea pigs from scurvy at the 6 gram level in 1931, was protective at a 6 gram level in 1932, and at a 4 gram level in 1933. It is apparent that the manufacturing methods now employed in the production of commercially canned tomato juices yield products of good antiscorbutic potency.

GUERRANT, N. B., RASMUSSEN, RUSSEL A. AND DUTCHER, R. ADAMS.

The Value of the Chemical Titration Method in Determining the Vitamin C Potency of Certain Food Substances. 1935, J. Nutrition, 9, 667.

Ten samples of fresh orange juice examined by the 2,6-dichlorophenolindophenol titration method for vitamin C estimation, were found to have an average ascorbic acid content of 0.5 mg. per ml., or a calculated minimum protective dose for guinea pigs of 1.0 ml. Two samples of canned orange juice were found to have an average ascorbic content of 0.294 mg. per ml., or a calculated minimum protective dose of 1.7 ml.

These results demonstrate that canned and fresh orange juice are excellent sources of vitamin C.

MACK, M. J., FELLERS, C. R., MACLINN, W. A. AND BEAN, D. A.

Vitamin C Content of Dairy Orange Beverages. 1936, Food Research, 1, 223.

Commercially canned orange juice was found to contain 213 International Units of vitamin C per ounce compared with 228 units in fresh orange juice. These values are equivalent to protective levels of 1.33 grams and 1.24 grams for the canned and fresh juice respectively. The determinations were made by the 2,6-dichlorophenolindophenol titration method.

Biological assay confirmed these results, 215 International Units per ounce being found in the canned product and 235 units in the fresh juice.

These data indicate that canned orange juice is an excellent source of vitamin C.

CASE II
ACETANILID SERIES

A series of case types where the dominant symptom is pain of nerve origin.

The Great Sciatic Nerve, involvement of which occurs in Sciatica.

SCIATICA

CHIEF COMPLAINT: Severe pain in back of thigh, coursing down the leg. Some tender areas.

HISTORY: Occasional arthritic pains; teeth and tonsils poor: pains in thigh slight at first.

PHYSICAL: Nutrition good; slight elevation of temperature.

SYMPTOMS: Gnawing pain, often worse at night; knee-jerk increased; patient walks with knee bent.

DIAGNOSIS: Sciatica secondary to system absorption of oral infection and toxins.

TREATMENT: (Symptomatic) Acetanilid, 5 grains repeated.

Solis-Cohen and Githens regard the relief of neuralgic pains afforded by acetanilid as one of its most striking manifestations. (Pharmaco-Therapeutics).

Bromo-Seltzer provides 3 to 3.5 grains of Acetanilid, plus its synergists—Caffeine and Bromides, in each teaspoonful dose. Caffeine gently invigorates the mental processes. Bromides promote relaxation of overwrought nerves. Citrates improve digestion, tend to replenish alkaline reserve and give to Bromo-Seltzer its effervescent palatability.

Bromo-Seltzer relieves pain effectively and economically.

Requests for sample and literature on Bromo-Seltzer receive prompt consideration.

Evaporated Milk—Effect of Irradiation on Vitamin A Content. 1936, Ind. Eng. Chem., 28, 1009.

The U. S. P. method of biological assay was employed to determine the vitamin A content of 2 mixtures of three nationally known brands of plain and of irradiated evaporated milk purchased on the open market.

It was found that 350 mg. of each mixture possessed the same vitamin A value as 0.5 mg. U. S. P. reference cod liver oil. Hence, both the plain and irradiated evaporated milk contained 4.28 International Units of vitamin A per gram (107 units per ounce).

GUERRANT, H. B., RASMUSSEN, RUSSEL A. AND DUTCHER, R. ADAMS.

The Value of the Chemical Titration Method in Determining the Vitamin C Potency of Certain Food Substances. 1935, J. Nutrition, 9, 667.

One sample each of fresh and canned tomato juice was tested for vitamin C by 2,6-dichlorophenolindophenol titration. The canned and fresh tomato juice contained 0.242 mg. per ml. and 0.157 mg. per ml. of ascorbic acid, respectively, with calculated minimum protective doses of 2.1 ml. and 3.2 ml. These results indicate that canned tomato juice ranks among the richest antiscorbutic foods.

HANNING, FLORA.

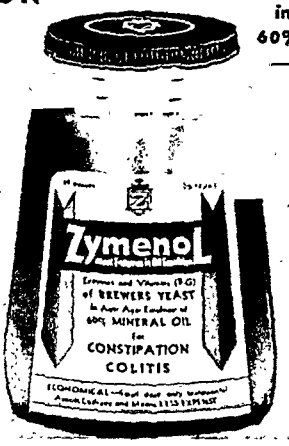
Comparison of the Biological and Chemical Methods for the Determination of Vitamin C in Canned Strained Vegetables and a Study of Its Variation from Year to Year. 1936, J. Nutrition, 12, 405.

Vitamin C was determined in commercially canned strained vegetables packed in growing seasons from 1930 to 1935. Assays made by the conventional guinea pig technique and by the sodium 2,6-dichlorobenzenone-indophenol titration method were in good agreement. The results, expressed in International Units of vitamin C per gram, are given in the accompanying table.

Considerable seasonal variation was noted in each product. Commercially canned tomatoes and spinach were found to be good sources and peas and green beans fair sources of vitamin C.

Product	Year Packed	International Units Vitamin C Per Gram: Bioassay	Chemical Titration
Tomatoes	1930	5.0	..
Tomatoes	1933	2.5	2.5
Tomatoes	1935		2.3
Spinach	1930	0.8	.
Fall Spinach	1931	1.0	.
Spring Spinach	1932	.6	.
Spring Spinach	1933	2.3	2.3
Spring Spinach	1934	1.8	1.8
Fall Spinach	1934	3.0	3.0
Spring Spinach	1935		1.9
Peas	1930	1.2	..
Peas	1932	1.9	..
Peas	1933	1.6	1.6
Peas	1934	1.2	1.2
Peas	1935		1.1
Green Beans	1930	0.6	.
Green Beans	1932	0.6	.
Green Beans	1933	0.8	0.8
Green Beans	1934	0.5	0.5
Green Beans	1935		0.3

GUERRANT, N. B., RASMUSSEN, RUSSEL A. AND DUTCHER, R. ADAMS.



The Value of the Chemical Titration Method in Determining the Vitamin C Potency of Certain Food Substances. 1935, J. Nutrition, 9, 667.

The vitamin C content of canned pineapple juice was determined in two ways: by biological assay using guinea pigs and by 2,6-dichlorophenolindophenol titration.

The minimum protective dose was found to be seven milliliters, indicating that 0.5 mg. of ascorbic acid is present

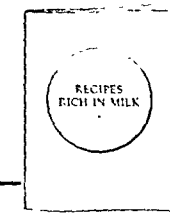
of every HUNDRED *cows*

produces soft curd milk . . .



Why this is so, no one knows—and the phenomenon would be of little interest were it not that soft curd milk is more readily digestible than ordinary milk and therefore is more suitable for the delicate or disordered digestive system.

Noteworthy in this connection and of special interest to gastro-enterologists is the fact that *all* Pet Milk is soft curd milk. The quality which nature has limited to the milk of one cow in a hundred is created in *every* ounce of Pet Milk.

Having ninety percent less curd tension than ordinary milk, Pet Milk provides maximum nutrition with a minimum of intestinal irritation.

It provides, also, uniform richness in all the food substances milk can be relied upon to furnish—extra vitamin D for better utilization of calcium and phosphorus, whey proteins of the character best suited to the patient allergically sensitive to milk, and, most important of all, the complete protection against milk-borne infection which only a sterile milk can give.

All these qualities are provided at less than the cost of ordinary milk—a combination of virtues unequaled in milk in any other form, strongly recommending the use of Irradiated Pet Milk in the dietary regimen employed in the treatment of gastro-intestinal disorders.

Samples and literature will be sent on request.

in 7 ml. of canned pineapple juice. Calculated from the chemical titration data, 7 ml. was found to contain 0.616 mg. ascorbic acid, a slightly higher value than the biological assay indicated.

These potencies are equivalent to 1.4 and 1.8 International Units of vitamin C per gram of canned pineapple juice, based on the biological assay and chemical titration data, respectively.

KOHMAN, E. F., EDDY, W. H. AND GURIN, CELIA ZALL.

Vitamins in Canned Foods. XIII. Canning Tomato Juice Without Vitamin C Loss. 1933, Ind. Eng. Chem., 25, 682.

The simplicity of this new process for canning tomato juice makes it available to nearly every producer.

Due to the carbon dioxide and other gases normally present in tomatoes, ebullition was reached by heating for a few seconds at a shallow depth at a temperature far below boiling. These inert gases served to remove the oxygen which the tomatoes may contain in such a short time that no significant loss of vitamin C could occur. Tests made on three batches of tomato juice prepared from three different batches of tomatoes of uniform vitamin C potency revealed no appreciable loss of vitamin C during the process.

FELLERS, CARL R.

Vitamin Content of Important Foods in the Child's Diet. 1935, Am. J. Pub. Health, 25, 1340.

The standard Sherman technic for vitamin C was compared with the 2, 6-dichlorphenol-indephenol method for this vitamin. The values obtained by the two methods were in good agreement.

The protective levels and ascorbic acid contents are given in the following table. These figures demonstrate that canned citrus fruits and canned tomato products retain their vitamin C content in high degree.

Fruit	No. of Samples	Protective Level For Guinea Pigs Grams	Ascorbic Acid Mg. Per Gram**

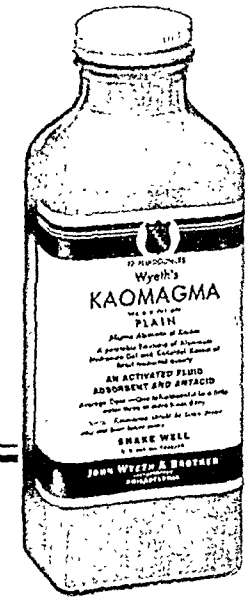
KAOMAGMA



MAGMA ALUMINAE ET KAOLINI

- *adsorbs intestinal toxins*
- *checks diarrhea*
- *stops dehydration*
- *soothes inflamed mucosa*

KAOMAGMA is a preparation of finest medicinal kaolin *activated to many times its normal adsorptive potency* by fluid dispersion in alumina gel. Kaomagma consolidates liquid stools and prevents the fluid depletion encountered in diarrheal conditions. It adsorbs gas, mucus and bacterial toxins, preventing further irritation to the intestinal mucosa. At the same time its definitely soothing and protective action upon the lining of the intestines allays inflammation, reduces soreness and discomfort, and hastens the return of normal bowel function.

AVAILABLE IN TWO FORMS:

Kaomagma Plain, for the use where intestinal disturbances are associated with diarrhea, and Kaomagma with Mineral Oil, for those cases in which constipation is present. Both forms are available in 12-ounce bottles.

PHILADELPHIA, PA. WALKERVILLE, ONT.

Immediate Symptomatic Relief and Remarkably Rapid Healing in

PEPTIC ULCER

Symptomatic Relief — the most important problem in the patients *mind* — is accomplished almost immediately when Creamalin is used in peptic ulcer. Epigastric pain promptly subsides with the first dose, and is held in dependable abeyance thereafter. Hyperperistalsis and pylorospasm are overcome, and the patient experiences complete subjective relief, with cessation of all symptoms in 24 hours.

Under Creamalin therapy, healing of peptic ulcer is unusually rapid. All roentgenologic evidence of the ulcer crater disappears in 7 to 12 days when Creamalin is administered by the "continuous drip" method, and in 3 to 6 weeks under oral administration.

Creamalin is a distinctive colloidal cream of aluminum hydroxide, notable for its acid-fixing powers. It neutralizes by adsorption 12 times its volume of N/10 HCl in less than 30 minutes (direct titration, Toepfer's reagent). Complete and sustained neutralization of the acid gastric juice, and consequently rapid healing, are thus assured. As the aluminum hydroxide is not absorbed systemically, alkalosis becomes impossible. Creamalin does not produce a secondary rise in acid gastric juice secretion.

Creamalin is indicated in the treatment of peptic ulcer, hyperacidity, and jejunal ulcers following gastro-enterostomy. Detailed literature, reprints of published reports, and clinical test samples on request.

HESS, ALFRED F.

Recent Advances in Knowledge of Scurvy and the Antiscorbutic Vitamin. 1932, J. Am. Med. Assoc., 98, 1429.

Prior to 1917 a diet of dried or canned foods was believed to lead to the development of scurvy. In 1918, it was shown that canned tomatoes retained the major portion of their vitamin C. Shortly after this Dr. Hess demonstrated that the factor responsible for the destruction of vitamin C was oxidation rather than heat, and what has commonly been considered the damaging effect of high temperature was largely the effect of oxidation. This discovery precipitated the studies of Kohman and Eddy and their collaborators, which have shown that vegetables and fruits can be canned with very slight loss of the antiscorbutic factor, if the deleterius effect of oxygen is excluded.

DANIEL, ESTHER P., KENNEDY, MARY H. AND MUNSELL, HAZEL E.

Relative Vitamin C Content of Orange and Tomato Juices Determined Chemically and Biologically. 1936, J. Home Econ., 28, 470.

Commercially canned tomatoes packed in New York State and labeled "Grade C" were strained and the juice assayed for ascorbic acid potency. The biological assays were carried out according to the Sherman et al, guinea pig procedure. The chemical titration method of Bessey and King was followed.

The minimum protective dose determined biologically was found to be about 3 ml., which compares favorably with 2.4 ml., the average minimum protective dose calculated from the results of the chemical titration. The average ascorbic acid content was found to be 0.21 mg. per ml. equivalent to 4 International Units per gram.

Thus, canned tomatoes rank high among foods in antiscorbutic value.

LAMER, V. K., CAMPBELL, H. L. AND SHERMAN, H. C.

The Effect of Temperature and the Concentration of Hydrogen Ions Upon the Rate of Destruction of Antiscorbutic Vitamin (Vitamin C). 1922, J. Am. Chem. Soc., 44, 172.

Juice from commercially canned tomatoes was used as the sole source of vitamin C in the work described in this paper because of its high concentration of this vitamin, and the uniform antiscorbutic potency to be found in tomatoes of the same lot.

Three ml. of the juice expressed from canned tomatoes was adequate for complete protection, which ranks canned tomatoes as one of the best sources of vitamin C.

GUERRANT, N. B., RASMUSSEN, RUSSEL A. AND DUTCHER, R. ADAMS.

The Value of the Chemical Titration Method in Determining the Vitamin C Potency of Certain Food Substances. 1935, J. Nutrition, 9, 667.

One sample each of fresh and canned grapefruit juice was assayed for vitamin C by the 2,6-dichlorophenolindophenol titration. The canned and fresh juice contained 0.41 mg. per ml. and 0.266 mg. per ml. of ascorbic acid, respectively, with calculated minimum protective doses of 1.2 ml. and 1.9 ml. These data indicate that both canned and fresh grapefruit juice are excellent sources of vitamin C.

FELLERS, CARL R. AND ISHAM, PAUL D.

Vitamin C in Canned Citrus Products. 1932, J. Home. Econ., 24, 826.

One gram per day (6 days a week) of canned orange juice gave full protection against scurvy over a 90-day test period; hence it must be ranked as one of the best food sources of vitamin C.

Since canned orange slices gave protection at slightly more than the 1 gram feeding level, this product must also be considered as an excellent vitamin C carrier.

The fruit used in this experiment had undergone from 6 to 9 months storage.

DAGGS, RAY G. AND EATON, A. G.

Vitamin C Content of Canned Tomato Juice. 1934, Ind. Eng. Chem., 26, 292.

The destruction of vitamin C which may occur during the canning process is slight indeed when one considers the ease with which this vitamin is oxidized.

Four milliliters of the commercial product or of the fresh juice from which it was made gave complete protection, while 3 ml. of the canned or the fresh juice, resulted in the development of mild symptoms of scurvy in guinea pigs.

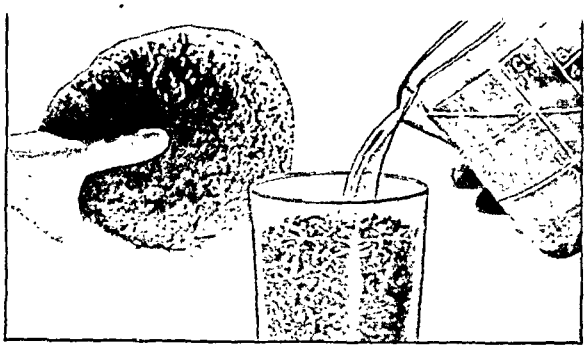
MACLEOD, GRACE AND BOOHER, LELA.

The Antiscorbutic Content of Some Preserved Foods. 1930, J. Home Econ., 22, 588.

Only the pulp of the canned pimiento was tested, the juice being drained off as is usually the practice in the household use of this product.

The protective level for canned pimiento pulp was found to be 2 grams, the same as that obtained for fresh grapefruit. This indicates a potency of 227 Sherman units per pound. Canned pimiento, therefore, ranks as one of the richest antiscorbutic foods.

» » EXERCISE « «



Exercise is one of the important factors in the treatment of constipation. Of equal importance are suitable diet and a regular habit time for bowel movement. Unfortunately, under the present mode of living, such strict regimen is difficult to enforce. While your patient may be inclined to forsake suitable diet and exercise, it is imperative that a daily bowel movement be maintained. Petrolagar assists in establishing a normal bowel movement as it mixes intimately with the feces to form a soft easily passed stool. By the use of Petrolagar habit time may be readily established and maintained.

PETROLAGAR LABORATORIES, Inc., Chicago, Ill.

Petrolagar is a mechanical emulsion of pure liquid petrolatum (65% by volume) and agar-agar. Accepted by the Council on Pharmacy and Chemistry of the American Medical Association for the treatment of constipation.

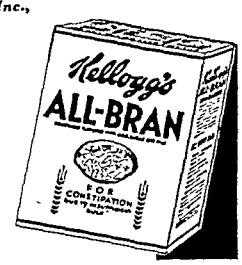
Petrolagar

MAKE THIS TEST IN YOUR OFFICE

See ALL-BRAN absorb water like a sponge

HERE'S a test you can make in a few minutes. It shows that Kellogg's ALL-BRAN acts, in the intestinal tract, much like a water-softened sponge.

Just fill a glass four-fifths full of ALL-BRAN. Pour water up to the brim of the glass. Soak fifteen minutes, and drain off the water. Feel the water-softened mass. It's as soft as a wet sponge.



Laboratory tests* show that Kellogg's ALL-BRAN absorbs at least twice its weight in water. Within the body, this softened "bulk" gently exercises and cleanses the system.

In addition to generous "bulk," ALL-BRAN supplies vitamin B, needed for intestinal activity. ALL-BRAN also furnishes iron for the blood. This natural laxative food is more satisfactory than the continued use of pills and drugs.

ALL-BRAN may be enjoyed as a cereal or cooked into recipes. Sold by all grocers. Made and *guaranteed* by Kellogg in Battle Creek.

*Tests made by Samuel P. Sadtler & Son, Inc., Analytical Chemists, Philadelphia, Pa.

Serve Kellogg's ALL-BRAN regularly for regularity

Human Requirements for Vitamins—Report of the Committee on Nutritional Problems. 1934-1935 Year Book, Am. Pub. Health Assoc., 25, 69.

Clinical evidence concerning the minimum vitamin requirements of the human is rather meager. In the past there has been a multiplicity of units used in expressing vitamin units in food products. The adoption of International units for vitamins A, B, C and D will help to simplify this in the future. The values given for vitamin requirements are those that prevent the appearance of clinical evidences of deficiency, but do not allow for a liberal allowance which may be desirable or even necessary for protection against deficiencies that have less well defined symptoms.

Vitainm A

One Sherman unit of vitamin A is equivalent to 1.4 International units. The minimum vitamin A requirement of an infant is probably close to 1500 International units per day. This amount is supplied by 750 ml. of human milk of the highest potency. Larger children and adults probably require increased amounts of vitamin A, but the exact quantities can only be postulated.

Vitamin B

In this country the occurrence of severe vitamin B deficiency, or beriberi, is extremely rare. The minimum daily requirement of vitamin B gradually increases from approximately 50 International units for infants to 200 for adults.

Vitamin C

The minimum amount of vitamin C required to protect an infant from scurvy is probably 100 International units per day. For adults the minimum protective dose is about 300 International units, equivalent to 15 milligrams of active ascorbic acid.

Vitamin D

The requirement of the infant has been fairly well established for vitamin D, as long as cod liver oil is used as the source of the vitamin. The minimum daily dose that will protect an infant from rickets is 250 Steenbock or 700 International units. The need for this vitamin is greatest during the first two years, after which it is greatly diminished. Various sources of vitamin D such as cod liver oil, irradiated ergosterol, and irradiated cholesterol do not possess the same relative values for the cure or prevention of rickets in rats and children.

Pellagra Preventing Factor

Methods used for the evaluation of vitamin G have not been a satisfactory measure of the pellagra preventive value of a food. There are probably several growth promoting factors present in vitamin G containing foods. Thirty grams of dried yeast daily, supplies the smallest amount of the factor or factors required for the prevention of pellagra.

Vitamin E

There is no conclusive evidence that vitamin E is required by the human. If this vitamin is essential it is probably adequately supplied in the diet.

PARSONS, HELEN AND STINE, LOIS.

Yellow Sweet Corn Has More Vitamin A Than White Corn. 1932, Agr. Exp. Sta., Univ. Wisc., Bull. 421, pp. 120.

The vitamin A content of commercially canned whole grain corn of two varieties was determined by biological assay method using albino rats as the experimental animal.

Packs of Golden Bantam representing the highly pigmented yellow varieties, and White Crosby representing white varieties, were found to have widely different vitamin A values. The yellow corn proved to be a rich

Convalescence from influenza, pneumonia and other illnesses associated with winter is a slow process, frequently requiring as much care as the acute attack. The dietary management is particularly difficult. Appetite and digestion are handicapped, yet the demand for nourishing food is increased. A diet which has proved beneficial at this time is one which supplies maximum caloric value in a palatable and easily digested form.

A Valuable Food in Convalescent Diets

Ovaltine is a food supplement which fulfills all the requirements of such a dietary regimen. It was originated, specifically, as a convalescent food. It is a highly nourishing and well balanced food. Ovaltine itself is easily digested and rapidly utilized, but in addition it increases the digestibility of the milk in which the beverage is made. It also contributes to the digestion of starches. It is palatable and helps to restore the appetite. Furthermore, Ovaltine taken at bedtime is a valuable aid in securing sound, restful sleep.

Recommend the use of Ovaltine at meals, between meals, and at bedtime during the convalescent period. It can be prescribed with confidence. Its merit is attested by over 40 years of continuous use in 57 different countries.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

source of vitamin A while the white corn was almost devoid of the vitamin.

It is concluded that the average serving of this yellow sweet corn (3 ounces) contains about the same amount of vitamin A furnished by an ordinary serving of butter (1/3 to 1/4 ounce).

ASCHAM, LEAH.

The Vitamin A Content of Pimento Pepper. 1933, Georgia Exp. Sta., Bull. No. 177.

Well ripened Perfection pimento peppers were canned in a commercial cannery. The vitamin A content of the product was determined by the Sherman method of assay, using rats as the experimental animal.

Fresh pepper was fed on a comparable basis with the dry and canned product. No demonstrable loss of vitamin A potency occurred during canning. Thirty mg. of the canned product (moisture content 93.4%) was found to be equivalent in vitamin A activity to 2 mg. of the dried product, the growth response on each dosage indicating that more than one Sherman unit of vitamin A was present.

Canned pimento pepper, therefore, is one of the richest known sources of vitamin A, containing 46 International units per gm. (696 units on dry matter basis).

STEENBOCK, H. AND SCHRADER, INEZ M.

Fat Soluble Vitamins. XXXII. The Distribution of Vitamin A in Tomato and the Stability of Added Vitamin D. 1931, J. Nutrition, 4, 267.

Commercially canned tomato juice fed in daily doses of 0.25 ml. cured ophthalmia, and 0.5 ml. doses both cured ophthalmia and restored approximately normal growth in young rats depleted of vitamin A. These data demonstrate that canned whole tomato juice is a good source of vitamin A.

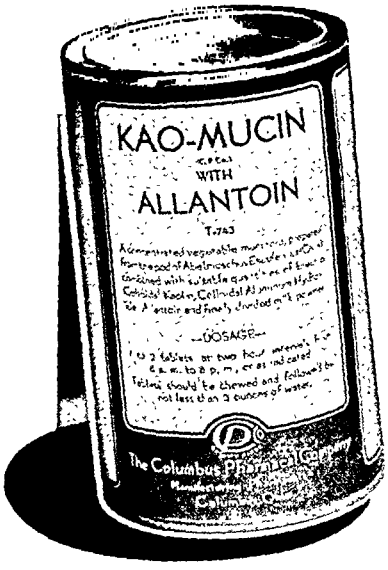
Tomato juice containing the pulp is 32 times as rich in vitamin A as filtered tomato juice (tomato serum).

CRIST, JOHN W. AND DYE, MARIE.

The Association of Vitamin A with Greenness in Plant Tissue. II. The Vitamin A Content of Asparagus. 1929, J. Biol. Chem., 81, 525.

Properly prepared test animals, when given 0.1 gram of canned green asparagus per day in addition to the vitamin A deficient diet, promptly recovered from the symptoms of vitamin A deficiency and grew at the rate of 32 grams in 8 weeks. A parallel test made with 0.2 gram of canned bleached asparagus resulted in rapid decline and death of the animals after the second week.

Thus, canned green asparagus is shown to be an excellent source of vitamin A while the bleached product is poor in this factor.



FRAPE, G. S. AND TREICHLER, RAY.

Losses of Vitamin A in Drying Fresh Raw Carrots and Sweet Potatoes and Canned Spinach. 1933, J. Agr. Res., 47, 539.

Canned spinach from which the liquid had been drained was found to contain 140 Sherman units of vitamin A per gram. This material contained only 14.7 per cent dry matter, hence, is a very potent source of vitamin A, containing 952 Sherman units per gram of solids.

Dried vegetables were reported to be inferior to raw fresh, or canned vegetables as vitamin A carriers. Upon drying: canned spinach, raw fresh carrots, and sweet potatoes lost 65, 80 and 29 per cent respectively of their vitamin A potency.

KAO-MUCIN *with* ALLANTOIN

Supplied in packages of 100 tablets.

The most advanced therapy in Peptic and Duodenal Ulcers

The soothing and corrective principles of Kao-Mucin, C. P. Co., (concentrated okra) are skillfully combined with the healing and cell proliferating qualities of Allantoin (the famous development from maggot therapy).

The extensive work on Allantoin of Dr. William Robinson of the U. S. Dept. of Agriculture, Washington, D. C., substantiating and confirming the original research of C. J. Macalister of England has been so widely covered in medical literature that the healing virtues of Allantoin need no further comment. Clinical cases by the thousands conclusively prove the value of Allantoin as a healing agent.

Kao-Mucin, C. P. Co., an outgrowth of the mucin idea, was introduced in 1935. Within two years more than a quarter million prescriptions were dispensed, and today the product is extensively employed in clinics, hospitals and in private medical practice.

WHAT IT DOES:

Kao-Mucin in the presence of dilute hydrochloric acid is reduced to a thick mucilaginous substance very rich in mucin content. The viscosity of this mixture together with the Colloidal Kaolin and Colloidal Aluminum Hydroxide forms a gel or coating which spreads itself over the stomach mucosa and duodenum. The soothing and protective effect upon the mucous membrane results in prompt relief from pain and other symptoms associated with gastric and duodenal ulcers.

In addition to the mechanical protective action, the powerful cell proliferant, Allantoin, is brought into direct contact with the ulcerated area. The viscosity of the mixture insures a constant supply of Allantoin and promotes the growth of new mucous tissue over the irritated and congested surfaces of gastric and duodenal ulcerations, in colitis, dysentery and in inflammation of the gastro-intestinal tract.

COMPLEMENTARY THERAPY

HYCOLA — Colloidal Aluminum Hydroxide in palatable wafer form. Removes excess acidity, not by chemical neutralization, but by colloidal adsorption. One 7½ grain wafer will adsorb approximately 5 c.c. of N/10 HCl.

Hycola assists the therapeutic action of Kao-Mucin with Allantoin.

Supplied in packages of 60 wafers.

The First NEW Practice. Meakins "Practice of Medicine" is the first book on practice that has added anything new and different to the books already in this field since Osler's book was published forty-four years ago. Opinions like this—Meakins is a different practice—have come to us almost daily from teachers and others whose opinions can be relied upon. Other typical comments are:

Arranged Different—Meakins starts at the head and goes downward just as you would examine a patient.

Based Upon Physiologic Function—Health depends upon the physiologic function of bodily organs. Disease is the disturbance of this function. Meakins is the first text-book on practice to feature this.

Profusely Illustrated. Books in every department of medicine are usually illustrated because the pictorial approach in teaching is usually the most effective. The exception to this rule are books on practice. Consult your own library and prove this. Meakins' practice is different Meakins' book is profusely illustrated—505 black and white illustrations—35 full pages in colors. Nothing like this elsewhere in texts on practice.

THE C. V. MOSBY COMPANY D. D. N. 4-37
3525 Pine Blvd., St. Louis, Mo.

Gentlemen: Send me Meakins "Practice of Medicine," charging my account. The price is $10.00.

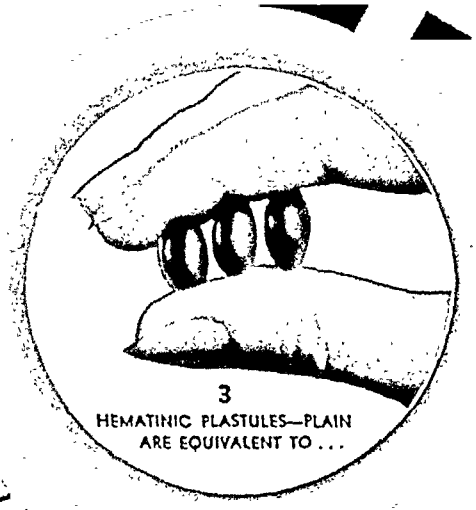
TESTAGAR
for BULK

More and more physicians are finding in TESTAGAR a valuable aid wherever BULK is indicated in gastro-intestinal disturbances.

TESTAGAR is *non-irritating* and meets all requirements in the treatment of functional chronic constipation, where a bulky lubricating substance is indicated.

TESTAGAR is a compound of the husks of Plantago Loeflingii Linn combined with the finest quality of AGAR-AGAR.

The Testagar Laboratories will be honored to receive your request for clinical test samples and further information.



The TESTAGAR LABORATORIES, Inc.
424 W. Elizabeth St. DETROIT, MICH.

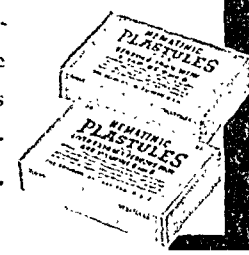
ated in 1905. He studied medicine in Freiburg-Baden and in Berlin from 1905 to 1910. He was an Interne in the orphan asylum with Prof. Dr. Finkelstein in Berlin; in the surgical department of the Diakonissenhaus in Freiburg, Baden; and in the general Municipal Hospital of Worms. He obtained his M.D. Diploma and license in Berlin, March, 1912. After having been a country physician and ship surgeon for a few months he served in the German Army for one year. Then he got the position of Assistant in Pathology at the Municipal Hospital Munich-Schwabing with Prof. Dr. S. Oberndorfer (Oct., 1913 to August, 1914). This activity was interrupted by the outbreak of the great war. He joined the army August 3, 1914. At first he was with an Ambulance, then reported voluntarily for the service in the trenches. For a long time he remained as a physician with the 12th Bavarian Infantry Regiment, especially at the Somme and Arras; then for 6 months he was pathologist to the 6th German army. After the war he became an assistant at the Medical Department of the Hospital Munich-Schwabing (2000 beds) with Prof. Dr. Otto Neubauer. For some time he was especially interested in psychogenic internal diseases; the result were publications on the diagnosis and treatment of psychoneuroses of the intestinal tract and a book on "Nervous System and Spontaneous Hemorrhages." Because of the many unexplained cases of gastric distress which were seen daily in his department he began thinking of the possibility of gastroscopy. After some training in esophagoscopy he constructed his first rigid gastroscope in 1922; in 1923 he published the "Textbook and Atlas of Gastroscopy" which remained the standard work for 13 years. It contained 118 colored pictures of almost all anatomical changes of the gastric mucosa. In the same year a paper on gastric tumors observed by gastroscopy appeared in the Archives of Internal Medicine, Chicago, translated by his friend, the late Dr. Will Rogers of Indianapolis. From this time on he was continually teaching physicians of all countries of the world the art of gastroscopy. He recognized that the rigid tube method was too dangerous to be introduced in the general practice. He tried to contact G. Wolf, manufacturer of endoscopic instruments in Berlin. He was able to understand Dr. Schindler's suggestions and to build numerous models which never were published until finally in 1932 they succeeded in the construction of the flexible Wolf-Schindler gastroscope. In the meantime Dr. Schindler had opened a gastro-enterologic practice in Munich (1924). He has published 50 papers on psychoneuroses, the effect of certain drugs on the gastro-intestinal tract, on X-ray relief examination, gastrophotography, and especially on gastroscopy. In 1934 the University of Chicago offered him a position as a Visiting Professor of Medicine and in 1936 he was appointed Associate Clinical Professor of Medicine at the University of Chicago, Attending Gastroscopist at Michael Reese Hospital, and Consulting Gastroscopist at Cook County Hospital.

Dr. Schindler married Gabriele Schindler, nee Winkler; two of his four children died in Germany; two (a boy of 14, a girl of 6 years) are living with him in Chicago. Mrs. Schindler has helped a great deal in the development of gastroscopy, since she assisted him in each of over 3000 examinations. He does not like to perform a gastroscopy without her assistance. In the United States he has carried out and recorded over 1050 gastroscopies. Already he has many excellent pupils all over the country.

HEMATINIC PLASTULES

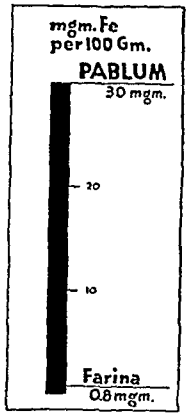
AN IMPROVED IRON THERAPY

16 Seven and One-Half Grain Capsules of Iron and Ammonium Citrates.



18 Five-Grain Blaud's Pills.

10 Five-Grain Capsules of Reduced Iron.



The soluble ferrous salt in Hematinic Plastules produces maximal results in small doses which obviates the unpleasant effects of the larger doses of ferric compounds. The average case requires only three Plastules-Plain daily. Hematinic Plastules are prepared by combining ferrous iron and vitamins B & G in soluble gelatin capsules. They are available in two types — Plain or with Liver Extract . . . . . Prescribe Hematinic Plastules for patients under treatment for hypochromic anemia and observe their rapid response without the usual side effects so frequently associated with the administration of large doses of other forms of iron. Send for samples for clinical trial.

THE BOVININE COMPANY, CHICAGO, ILLINOIS

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders *is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.*[1] *"Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."*

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embryo, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

Carcinoma at the Cardia, a Roentgenological Discussion

By

WILLIAM H. STEWART, M.D.*

NEW YORK, NEW YORK

DR. Urban Maes of New Orleans, in a recent article in the Annals of Surgery has referred to the "Tragedy of Gastric Carcinoma." This title so aptly expresses what we see daily in any large hospital that I have been moved to use it in this discussion of carcinoma at the cardia.

It is possible to cure carcinoma of the stomach only if it is discovered early, before dissemination has occurred. There are at least a dozen reasons why carcinoma of the stomach, especially when it involves the fundus and cardia is not recognized early. Probably the most important one is that the family physician has not become sufficiently cancer conscious. He has a tendency toward optimism and too often prescribes some simple remedy and permits the patient to go without adequate study, especially if he is in a busy office or clinic. Such a patient forty-five years old or over may consult you complaining of weakness, perhaps with some slight indigestion. He may come into your office and merely say "doctor, I feel so tired," or "I am not able to play golf as I used to." Such symptoms are not alarming yet they may be the only hint that one is dealing with a gastric carcinoma, for it is true that at this time the early diagnosis can be made but only by roentgenographic examination. Do not wait until your patient has dysphagia, loss of weight and appetite, regurgitation of mucus, vomiting of blood and anemia, for these symptoms indicate that it is now too late for anything except the most radical surgery and the peril of a high mortality.

A second important reason and the most tragic of all is that carcinoma of the stomach, unless it involves the inlet or the outlet, or is well advanced, gives few symptoms except this one of weakness mentioned above. You will fully realize this when you observe the roentgen studies of the cases which illustrate the article. You will note at once that the vast majority show well-advanced lesions, practically inoperable, and yet these patients are typical of the stage of the disease that we meet daily.

What is more tragic than the following experience:

A lady on a golf course playing a full eighteen holes, while her husband is teamed up with you in a foursome; that same evening she calls on you complaining of a slight indigestion. Her husband, a doctor, has sent her with the remark: "Go over to Dr. Stewart and let him look you over, he may be able to tell you what, if anything, is wrong." When I placed her behind the fluoroscopic screen after the barium meal I saw a large inoperable carcinoma of the stomach.

It has been said that a prominent roentgenologist in the West came back from Europe feeling rather tired after attending a meeting of the International Radiological Society held in Stockholm. He complained of a few gastric symptoms but apparently nothing serious. Someone suggested that he have a series of X-ray films made. This was done and when they were placed before him on the illuminating box he saw his own stomach involved by an inoperable carcinoma. Again I say that is tragedy.

You may well ask, What are we to do about it? There is one thing that can be done and that is to advocate a routine X-ray examination in all patients of forty-five years or over who do not seem to be up to par and to repeat this examination periodically. Every one can appreciate at once the possibility of picking up a carcinoma of the stomach in its early stage by this method. Why is it not done more often? There are many reasons:

First, the physician is reluctant to send the patient to the roentgenologist because he does not wish to give the patient the impression that he is an alarmist. Many patients, when referred for X-ray examination come reluctantly believing that all this fuss is unnecessary, that the doctor is too scientific and is putting him to useless expense, when all he needs is a simple tonic. This question of expense is a serious one and often is the reason why so many patients fail to have a roentgenographic examination even when it is recommended by the family physician. Unfortunately, it is a general impression that the roentgenologist overcharges for his work. I have heard this complaint many times during my career. My answer has always been that no reliable X-ray specialist will refuse to examine any case referred to him. If asked to do so, he will gladly adjust his fee to the means of the patient.

Second, many surgeons and internists believe they can detect early carcinoma at the cardia on the fluoroscopic screen. Their experience, however, usually is limited and their negative diagnosis as a rule cannot be relied upon, for it is generally conceded that many of the finer shadows are not detected fluoroscopically and that we must rely upon the films for the detection of an early lesion. Fortunately, the better men realize the limitations of fluoroscopy so that when they have a questionable case they usually refer the patient to a competent roentgenologist for a check-up.

The third difficulty is the inexperience and unreliability of many medical men posing as specialists in roentgenology. Many of them who have opened up elaborate offices with the latest equipment and demand high fees are nevertheless not competent to make a negative diagnosis, especially in malignancy of the stomach. Some of these so-called roentgenologists are nothing more than "picture makers" and do not deserve the confidence of the medical profession. Leaders in the specialty have long recognized these conditions and have now established the American Board of Radiology which is making every effort to control this evil. All men who desire to be rated as specialists in radiology are required to pass an examination before this board. It is not easy, but it is fair. The time will soon come when all hospitals will require a certificate from this board before a staff appointment will be

*Radiologist, Lenox Hill Hospital, New York, N. Y.

Submitted February 27, 1936.

Fig. 1. E. B., female, 47 years. Three month history of indigestion, belching, heartburn, occasional vomiting. Beginning dysphagia and weight loss. *X-ray Findings:* Carcinoma of the fundus—process involves the cardia.

made. In this manner it is believed that the incompetent will gradually become eliminated.

There is an additional reason why the early diagnosis of carcinoma of the stomach is not made, namely, the slow insidiousness of the disease. It is this which often prevents the patient from consulting his physician at an early date. It has been said that investigation at the Mayo Clinic showed that *even among doctors* the average delay between the onset of the symptoms and the seeking of medical advice was fourteen months. The only way to overcome such a condition is to continue educational propaganda among the members of our profession and the general public.

What, then, is the correct technic to use in the X-ray examination of the esophago-gastric junction?

At the start it is well to appreciate that only in rare instances is the malignancy limited to the cardia. As a rule it is either a carcinoma of the esophagus spreading downward or more commonly a lesion in the fundus of the stomach spreading upward. We stress this point because there are a number of cases on record in which the upper part of the stomach was not included in the X-ray examination. As a consequence a lesion at the cardia was missed. If the esophagus is carefully examined in every case this is not likely to happen. Although this paper deals primarily with the fundus and cardiac portion of the stomach it is worth while to describe how we first examine the esophagus.

METHOD FOR ESOPHAGUS

The patient is requested to swallow a small amount of a mixture of Zoolak and barium of creamy consistency. During the act of swallowing he is observed in the right anterior oblique position under the fluoroscopic screen. As the patient continues to swallow he is rotated until a position is reached which best reveals the lesion if one is present. By means of a switchover arrangement from fluoroscopy to radiography, we immediately snap a film which will include the abnormal shadows. If satisfactory visualization is not obtained by use of the Zoolak and barium mixture, or if we are looking for varicosities or change in the rugal markings in the lower third of the esophagus we use a thick paste consisting of mucilage of acacia and barium. We have practically discarded the use of capsules except as an aid in locating non-opaque foreign bodies. They are apt to stop at any point in their downward trip without necessarily being arrested by a real organic obstruction. Any slight spasm or lack of lubrication will obstruct them and sometimes it is remarkable how long they will remain in one locality without being held by any pathologic condition.

Many extensive lesions have been found which cause little or no symptoms of dysphagia. For this reason the cardiac orifice and lower esophagus are watched with special care for any perceptible infiltration or contraction of the lumen.

The roentgenographic examination of the stomach requires a technic as exacting as any surgical procedure. A certain standardization is essential so that a lesion may not be overlooked but there must also be some necessary variation of technic whenever the pathological involvement is thereby better demonstrated. Careful preparation of the patient is essential and most important of all is that the stomach be as empty as possible when the examination is conducted.

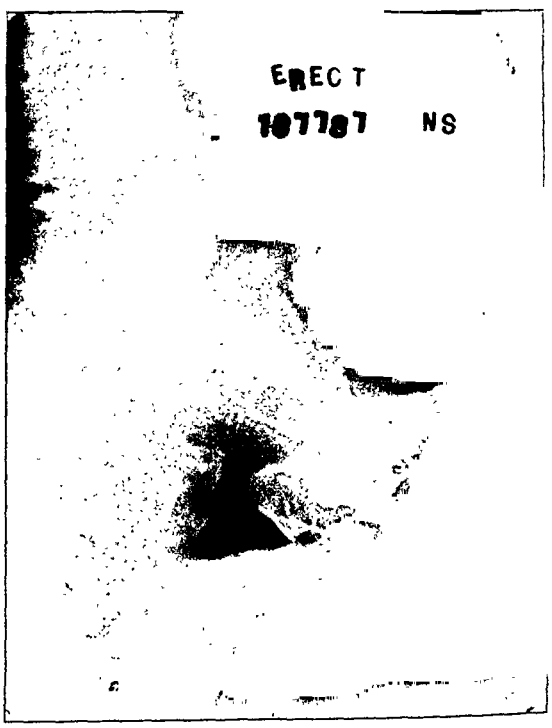

Fig. 2. N. S., male, 52 years. *Three month* history of pain, nausea and weakness with increasing dysphagia. A mass was present in the left upper quadrant. *X-ray Findings:* Extensive carcinoma of the fundus and at the cardia.

Fig. 3. J. S., male, 67 years. Burning in epigastrium for nine months. Pain and dysphagia for three months. Palpable mass in left epigastrium. *X-ray Findings:* Neoplastic involvement of cardia with dilatation of the esophagus. Autopsy showed a primary carcinoma of the splenic flexure with secondary involvement of the cardia.

METHOD FOR STOMACH

The examination of the stomach, and especially of the cardiac portion, begins as soon as the first barium enters the stomach. The patient is not permitted to take more than one swallow until certain observations are made. This barium should reach the mid portion of the stomach almost immediately, outlining the rugae and collecting in a pool in the lower stomach, leaving the cardiac end outlined by the gas bubble. By palpation the entire stomach is outlined under the screen so that the pliability of the gastric wall can be tested and some idea obtained regarding possible lesions of the anterior or posterior wall. The upper stomach is examined with special care for any abnormality in the appearance of the rugae. Tender points on palpation are localized, and masses and areas of resistance are looked for. Extrinsic masses or adhesions are sometimes more easily recognized when the stomach is only partially filled.

Special study of the gastric mucosa is carried out at this time. The pattern of the gastric mucosa is more difficult to outline than that of the colon due to the fact that complete contraction of the stomach is never present. When the colon evacuates, barium traces are left which are sufficient to outline the contracted lumen of the bowel and the appearance is rather constant and characteristic. The empty stomach is a relaxed bag and the fundus has the largest lumen of all. In addition, some slight amount of gas and watery gastric secretion are present which obscure the detail of the mucosal folds. Direct palpation is difficult because of the costal arch. The best results in the study of the gastric mucosa are obtained with only a small quantity of barium and films have the best detail when made with short exposures. Such films should be routinely made as part of every gastric examination. The relief pattern of the gastric rugae in the fundus conforms to a fairly regular standard, any marked variation or deviation from which requires careful investigation. The rugae form parallel folds producing a striped appearance, alternating with ribbons or strands of barium filling the valleys between the rugae, the entire pattern exhibiting regularity and uniformity. When organic disease is present there is marked irregularity and an abnormal or bizarre pattern may be revealed. Actual loss or absence of relief markings may be demonstrated, the parallel folds being replaced by irregular criss-crossing or radial striation, this deformity being constant. In order to diagnose early carcinoma of the posterior wall of the cardia it is necessary to obtain this visualization of the gastric rugae.

It is essential to demonstrate a normal pattern as well as normal filling of the distended stomach before a case can be reported as negative for cancerous involvement. Re-examination often is necessary and should be done more frequently if there is the least suspicion of any abnormality. There is no better method to avoid mistakes than repeating an examination regarding which there is any lingering doubt.

When a patient swallows a fluid barium meal it passes down through the esophagus at a rapid rate as far as the lower third where there is momentary hesitation before it enters the upper end of the stomach. A column of barium three or four inches high collects, and unless more is swallowed, it disappears into the stomach in a few seconds. The lower esophagus presents a constant, characteristic swaying motion as well as an additional wave motion of peristalsis. The cardiac sphincter regulates the passage of the barium into the stomach, the discharge proceding in a characteristic spurting fashion. If conditions are unusu-

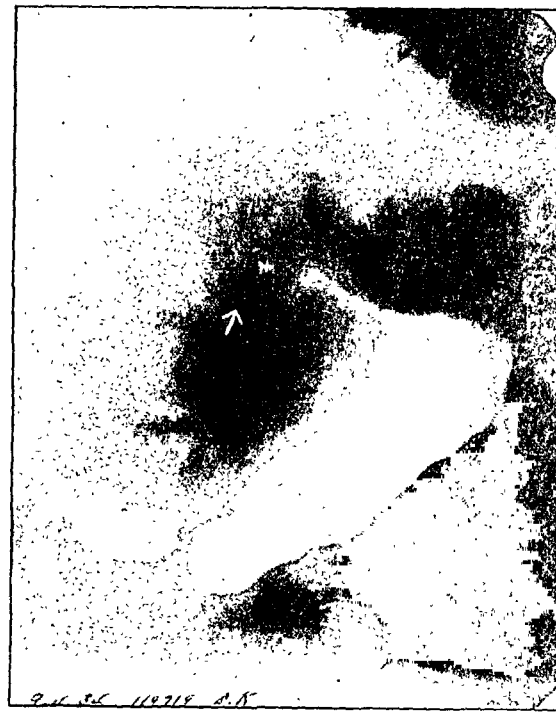

Fig. 4. D. K., male, 53 years. Epigastric pain for eight months. Thought to be angina. No dysphagia. *X-ray Findings:* Extensive malignant involvement at the cardia.

Fig. 5. A. B., male, 70 years. Nausea, vomiting, anorexia and weight loss for six months. Palpable mass in left upper quadrant. No dysphagia. *X-ray Findings:* Extensive carcinomatous involvement of the cardia without obstruction to the esophagus.

ally favorable, rugae may be visible in the lower esophagus. The length of the cardiac sphincter should be noted as well as the general outline of the esophagogastric junction.

In studying the roentgen signs indicating involvement of the cardia we must first discuss those which indicate the early lesion, and then enumerate the findings in the more advanced cases. For reasons which we have already stated, few cases have been picked up at what we call an early stage. *These have shown a slight delay in the passage of the barium through the cardia, with lack of normal spurt, the stream slowing down and giving a general impression of stiffness and induration.* This varies from a mild degree to distinct canalization. The most reliable observation is a change in the rugal markings as already described. Another finding sometimes seen is a budding projection on the lesser curvature at or near the cardia; this is rare but actually represents a cancerous crater outlined by the barium. Often there is a slight roughening and blurring along the lesser curvature as we approach the cardia. It is very significant.

The more advanced X-ray signs may be enumerated as follows:

1. Dilatation of the lower esophagus with abnormal retention of barium in its lower portion. 2. Opaque material passing through the esophageal orifice in a continuous stream. 3. Stiffness and narrowing of the esophagus or unchanging canalization through a tumor. 4. Frozen mass, the infiltration preventing the normal movements of the lower esophagus. 5. Tumor visible in gas bubble with deformity of magenblase. 6. Distorted rugal pattern with mass visible after distention of stomach by the full meal—contracted gastric lumen. 7. Forking of barium stream as it passes over the tumor. 8. Gastric hypermotility. 9. Esophageal antiperistalsis. 10. Increase in the space between the fundus and the diaphragm. 11. Roughening or projections seen on the lesser curvature near the cardia.

Let us consider each of these signs individually.

1. The lower esophagus may be dilated to twice or three times the normal size of the lumen but this dilatation is never as great as with cardiospasm. Even slight increase in the size of the lumen is of consequence and deserves study to ascertain the cause. There often is retention of barium. If the patient finds that certain solid foods, such as toast, are especially difficult to swallow, this material if obtainable, is used to test the swallowing ability, being followed by barium solution to demonstrate the obstruction.

2. Normally the esophagus discharges its contents in a peculiar, characteristic spurt-like manner. When the sphincter is infiltrated by malignant disease the fluid empties in a continuous stream. There is no preliminary hesitation of the barium in the lower esophagus but immediate and continuous emptying.

3. The sphincter is lengthened and a narrow canal is seen passing through the tumor mass. The channel as a rule is irregular and has jagged margins.

4. The mass of infiltration causes fixation of the esophagus so that the characteristic swaying and peristaltic movement of the wall is absent.

5. The gas bubble in the stomach is normally a hemispherical black shadow above the fluid level. When

Fig. 6. G. S., male, 52 years. Vague gastric symptoms, loss of weight and weakness. No dysphagia. Anemic. *X-ray Findings:* An extensive malignant growth at the cardia.

Fig. 7. F. M., male, 47 years. For last six months has had a peculiar heavy sensation in lower end of esophagus. Increased by excitement or worry. Most often appeared early in morning. No difficulty in swallowing except when eating an apple. Some weakness and loss of weight. *X-ray Findings:* Extensive malignant growth at the cardia involving at least four inches of the esophagus.

the patient is standing erect a mass may often be distinguished causing an irregular mottled density encroaching upon the inner angle of the magenblase.

6. After a swallow of a barium meal the mucosal pattern of the gastric rugae in the cardiac portion of the stomach may be seen to be altered. The normal regularity is lost and instead a bizarre, distorted, jumbled appearance may be demonstrated. When the stomach is completely filled by a full meal, the lumen in the cardiac portion is narrowed and contracted.

7. As barium trickles into the stomach the stream often forks over the mass in the cardiac portion.

8. Malignant involvement of the cardiac portion of the stomach is accompanied by hypermotility of the meal so that the stomach empties quickly; the meal pours out through the pylorus at a much accelerated rate.

9. Antiperistalsis in the lower esophagus. As many as two or three waves are simultaneously visible, depending upon the degree of obstruction.

10. Many positive cases show an unusually wide space between the top of the fundus and the left diaphragm. It is due to infiltration of the stomach wall and lack of free movement of the left diaphragm.

11. Roughening and irregularity along the lesser curvature in the region of the cardia may be noted. In addition there may be single or multiple projections in the same locality.

The clinical history and X-ray findings are of more importance in the diagnosis of gastric lesions than in many other fields of clinical investigation. A hasty roentgenographic examination without adequate knowledge of the clinical possibilities will result in a large percentage of failures. Knowledge of a physical finding or certain clinical information may be the reason for the extra effort that leads to a successful "confirmation."

Because this paper deals only with the diagnosis of carcinoma of the cardiac portion of the stomach careful consideration must be given to the differential diagnosis.

DIFFERENTIAL DIAGNOSIS

1. *Cardiospasm:* Spasm in any part of the intestinal tract is one of the most disturbing factors encountered and one of the most difficult to differentiate. Repeated examinations are often helpful in determining the permanency of the defective filling. The deformity of spasm may persist throughout several examinations and this is especially true of cardiospasm. To induce spasm, an irritant such as pepper may be given with the opaque material. The filling defect of cardiospasm occurs in the esophagus usually above the diaphragm and is typically cone-shaped or funnel-like with smooth margins. The dilatation may be extreme and even slight involvement shows greater dilatation than accompanies carcinoma. Fluid levels may be visible and splashing can be demonstrated. The clinical history and duration of the complaints usually covers a period of years. With carcinoma a mass is demonstrated producing a filling defect with ragged borders. The margins of the canal are rough, while the dilatation is slight. The barium passes through the canal in a continuous trickling stream. The history of dysphagia usually is shorter.

2. *Diverticulum of the lower esophagus is* rare. When demonstrated the shadow is disclosed beyond the lumen and it lacks any of the signs enumerated indicative of cancer.

3. *Varix* causes notching of the edge of the lower esophageal outline and masses of varices sometimes produce characteristic filling defects of the lumen with enlargement and deformity of the mucosal folds. Occasionally slight dilatation is seen.

4. *Lesions producing external pressure.* Rarely metastatic disease may form masses in close relation to the cardiac sphincter and cause dysphagia and other complaints which simulate intrinsic disease. Roentgenographically the differentiation is usually simple. The esophagus is displaced and while there may be some moderate obstruction the characteristics of malignant involvement are missing.

5. *Hernia of the diaphragm.* A part of the cardiac portion of the stomach may be invaginated into the thorax through an enlarged esophageal hiatus. This may produce dysphagia, although most of these patients have few if any symptoms and the lesion is usually an incidental finding. The hernia is best demonstrated when the patient strains while holding the breath during the time that the barium meal is in the stomach.

6. *Ulcer of the cardiac portion of the stomach.* Benign ulcer may be encountered high up on the lesser curvature or even in the lower esophagus, and occasionally in a gastric hernia. The mucal folds show radial striation. The larger the crater, the more likely is malignancy to be present, especially so if the crater

does not promptly and permanently disappear after medical treatment.

Pneumoperitoneum is occasionally of value in the differential diagnosis. If there is not too much obstruction the sausage skin method may assist in obtaining detail sufficient to recognize malignancy.

Adhesive bands may cause deformities difficult to differentiate from cancer. As a rule, they produce a smooth constriction and have a much longer history than is typical of cancer. The roentgen indications of cancer are usually absent. Weight loss is negligible.

One could hardly close this discussion without a word on the value of the esophagoscopic and gastroscopic examinations. Such instrumentation is not relished by the patients and few doctors have the ability to persuade a patient to submit to such procedure when symptoms are few and trivial. The danger of hemorrhage and rupture of the esophagus must be considered. When justifiable symptoms appear, these examinations are of great value, especially if supported by the roentgen findings. At this time, however, as already stated, it is too late for permanent surgical relief.

In this small series of twenty cases of carcinoma at the cardia, the duration of symptoms varied from six weeks to one year. Loss of weight and weakness was mentioned as a principal complaint in fifteen cases. Dysphagia was next most common, being noted in twelve. Seven cases with well marked involvement of the cardia had no dysphagia. Pain was referred to the pathological site in thirteen. Vomiting was noted in only seven and bloody vomitus in four.

We trust that we have not created the impression that we are infallible in the early roentgen diagnosis of carcinoma at the cardia. Even with the greatest possible skill certain early lesions of the cardia may be undiscovered. However, this fact should stimulate our efforts and encourage us to greater patience and persistence. Only in this way will an increased percentage of these patients have their disease discovered at a stage when radical surgery may offer a hope of cure.

Studies on the Blood Esterase*

By

R. GINSBERG, M.D., R. KOHN, M.D.

and

H. NECHELES, M.D.

CHICAGO, ILLINOIS

I

IN the rather voluminous literature which arose around the "vagusstoff" of Loewi (1) and the enzyme, choline-esterase (2), little has been reported regarding the factors which maintain and which might vary, the level of this enzyme in the blood.

These facts are well known: There are broad variations in the choline esterase level of the bloods of different species (3, 4). There are narrower, but definite, differences between individuals of the same species (4). There are differences in the choline esterase level of the blood of the same individual at different times (4, 5), independent of any known cause. There is no regular diurnal variation in the choline esterase level of the blood. There is no relationship to age, sex, or weight. It is not affected by excitement, menstruation, pregnancy, diet, exercise (5) or fasting (16).

The earlier workers have reported no relationship of the choline-esterase level of the blood to disease processes. However, from the work of Vahlquist (5) and perhaps from that of Brickner (6) there does appear to be a relationship, significant or otherwise, between the choline esterase level of the plasma and certain pathological conditions. Vahlquist (5) showed a definite low choline esterase level in long standing active tuberculosis and in other diseases producing cachexia. He also reported that patients with gastric ulcers and bronchial asthma have choline esterase levels somewhat lower than normal. However, he feels that in the latter cases ("vagotonics") the low esterase values bear no casual relationship to the conditions, since the values are not as definitely lowered as in tuberculosis. Brickner (6) has shown that in cases of active multiple sclerosis the plasma esterase is markedly decreased, that the value is highest at the beginning of periods of inactivity, that it then decreases during periods of inactivity, but never to the low level of the active cases. However, we cannot definitely attribute the low esterase level found by Brickner to a decrease in the choline-esterase since there is a difference of opinion as to the specificity of the choline-ester splitting enzyme. Stedman claims to have purified choline-esterase from plasma so that it has no effect on methyl butyrate (17). Shaw (7), believes that there are at least two esterases present in blood plasma, both capable of splitting simple esters (methyl and ethyl butyrate, tributyrin and acetylcholine), but only one of which is inhibited by eserine. He states that the purified enzyme of Stedman is not, in fact, choline-esterase since it is not inhibited by eserine. Vahlquist (5) believes that there is only one non-specific esterase in blood plasma capable of splitting choline esters as well as other simple esters. In making his titrations, Brickner used methyl butyrate as the substrate. Unfortunately, however, he did not carry on parallel titrations using acetylcholine as sub-

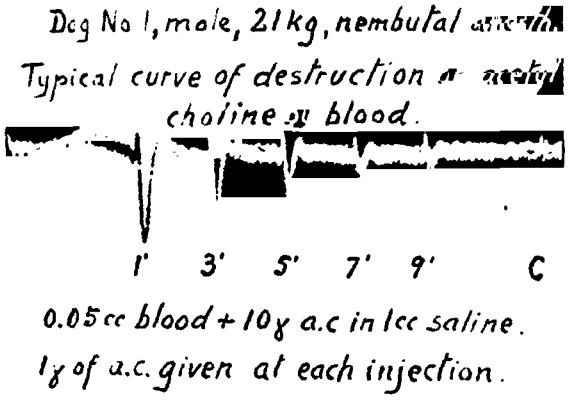

Fig. 1

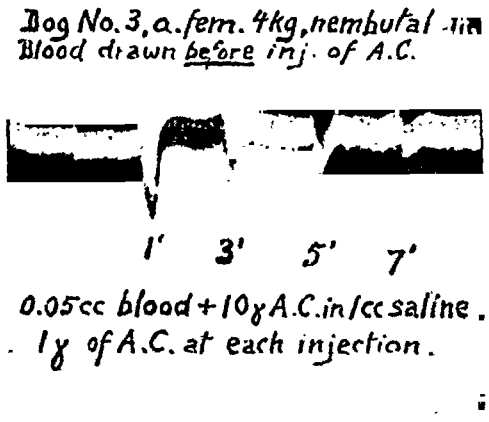

Fig. 3

strate nor did he study the effect of eserine upon this esterase.

Thus far, therefore, the above mentioned conditions are the only ones in which some change in the choline-esterase level of the blood has been postulated. In quite a number of other acute and chronic diseases, including neoplasms, no correlation has been found.

Several attempts have been reported to alter the choline-esterase level of the blood in experimental animals and man. R. Tsuji (8) found that subcutaneous injections of adrenaline, painful skin stimuli, "stimulation of the adrenals," faradic stimulation of the vagus, injection of choline intravenously, all caused a decrease in the acetylcholine splitting property of the rabbit's serum. However, samples taken at similar intervals when the rabbit had not been interfered with showed a similar fall of its choline ester splitting properties. Obviously, the author could not draw any conclusions from these findings.

Govaerts, Cambier and Van Dooren (9) found that in the dog and in man injection of acetylcholine does not change the concentration of blood esterase, and Ingvarsson confirmed this in the dog (10).

Our interest in this problem has its origin in some earlier work (11, 12, 13) in which it was shown that small doses of acetylcholine, comparable in amount with that liberated in the stomach by vagal stimulation, caused a marked contraction in the vessels of the stomach. It was indicated then that overproduction or continuous production of acetylcholine might have a causal relationship to peptic ulcer in that prolonged vascular spasm in the more susceptible areas of the stomach—the distal part of the lesser curvature and the duodenal cap which contain end arteries—might lead to anoxemia and digestion.

It was our opinion that if the factors which maintain the choline-esterase level of the blood could be determined and then experimentally altered much might be learned of the rôle of this blood esterase in maintaining the equilibrium of the autonomic nervous system and perhaps in the genesis of peptic ulcer.

Opinions as to the importance of the choline-esterase of the blood are now much at odds. Oppenheimer (14) supposed it to be a cellular waste product. Tsuji (8) believed it to be an extremely important mechanism in maintaining the balance of the vegetative processes. Vahlquist (5) questions its rôle in the finer regulations of the vegetative functions, but feels that it serves as a protective mechanism against an accumulation of acetylcholine in the blood. Brickner (6) states that the high esterase level in the blood of patients with multiple sclerosis during remissions, may be associated with repair of the myelin sheaths. Stedman (4) states that "the concentration of this

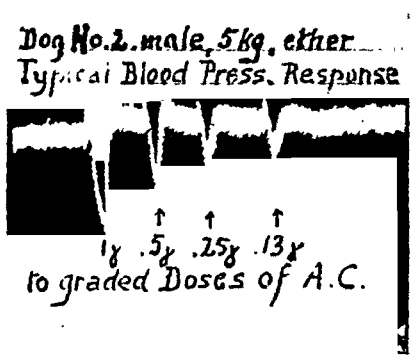

Fig. 2

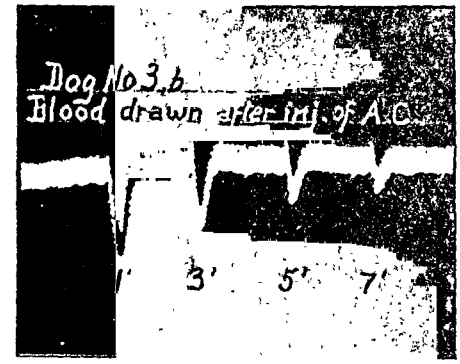

Fig. 4

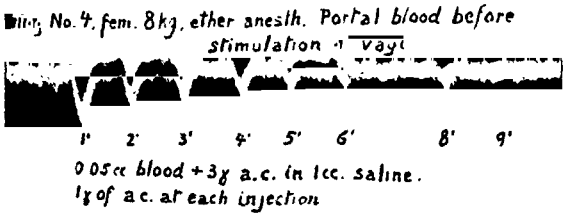

Fig. 5

enzyme in the blood must be regarded as one of the factors which control the activity of the heart. . . ."

With the purpose of observing their effect upon the choline-esterase level of the blood, the following experiments were carried out.

METHODS

The usual methods for acetylcholine assay are four in number. (1) By comparing the degree of shortening produced by a given concentration of acetylcholine when acting on muscle such as the eserinized back muscle of the leech or the frog rectus to that produced by a known concentration of acetylcholine. (2) By its effect on the perfused frog's heart. (3) By the extent of the evanescent drop in systemic blood pressure produced by intravenous injections of acetylcholine. This drop is proportional within narrow limits to the amount of acetylcholine injected. (4) By chemical methods: (a) Titration of the acetic acid produced in the hydrolysis of acetylcholine. (b) Gasometric determination of the amount of CO_2 released from carbonates (such as carbonate-Ringer solution) by the acetic acid liberated in the hydrolysis of acetylcholine.

For our purpose the third method was most suitable, since we required a method by means of which rapid and frequent assays could be carried out. By this method rather small differences in esterase level could be detected, as will be described later.

Two dogs were used for each experiment designated as subject and test dog. The experiments described below were carried out on the subject dog from which bloods were drawn before, during and after the procedures named. The enzymatic activity of these bloods were determined using the test dog. This test represents a modification of the one used by Govaerts, Cambier and Van Dooren (9).

PROCEDURE

A. Constant Injections of Acetylcholine (4 experiments performed). The effect of constant injection of acetylcholine on the esterase level of the blood was studied. The rationale of this procedure finds justification in the fact that administration of substrate often alters the elaboration of the corresponding enzyme in the organism (19).

Constant injection of acetylcholine into the femoral vein of the subject dog anesthetized with nembutal or ether was carried out by means of a modified Woodyat pump. Carotid blood pressure was recorded in the usual manner. Blood was drawn from the femoral artery, before, during and after constant injection of 375 to 600 mg. of acetylcholine over a period of about six hours. Liquoid* (0.15 mg. per c.c. blood) was added to prevent clotting.

The principle upon which the essay of choline-esterase was based is that intravenous injection of acetylcholine produces an evanescent drop of blood pressure proportional within certain narrow limits, to the amounts of acetylcholine injected, so that differences can be elicited in response to rather small variations in the amount of acetylcholine injected.

For the assay of the esterase in our blood samples, the test dog was anesthetized, one of its carotids was prepared for blood pressure recording, and one of its femoral veins was cannulated and connected by means of rubber tubing to a container from which measured quantities of saline could be released into the vein. Acetylcholine solution (10 gammas per c.c.) was prepared. The sensitivity of the test dog was determined by noting the difference in fall of blood pressure to graded doses of acetylcholine which were injected into the rubber tubing connected to the femoral vein and then washed into the vein by releasing 2-4 c.c. of saline from the container. It was generally found that variations of about 0.15 gamma can be differentiated in this manner within a range from 0.25 gamma to 2.0 gamma. The sensitivity of the dog was repeatedly tested during the experiment.

From 0.02 to 0.06 c.c. of the blood to be tested was pipetted into a watch glass, 1 c.c. of acetylcholine solution (10 gammas per c.c.) was added, and the two substances were well mixed for 15 seconds. The mixture was then drawn up into a tuberculin syringe, the needle of the syringe was introduced through the rubber tubing into the cannula of the femoral vein, 0.1 c.c. of the mixture was injected into the cannula and washed into the vein at the end of the first minute and every other minute thereafter for from 9 to 11 minutes. The first injection resulted in an evanescent drop in blood pressure almost equal to that produced by the injection of 1 gamma of acetylcholine alone, since in that short time the choline-esterase in the blood-acetylcholine mixture had not hydrolized much of the acetylcholine in the syringe. The drop in blood pressure became less with each succeeding injection due to the progressive destruction of acetylcholine by the blood with which it was mixed.

The blood drawn before an experimental procedure was tested first. An amount of this blood was used which would bring about complete destruction of the 1 c.c. of acetylcholine (10 gammas per c.c.) as shown by an absence of blood pressure response to further injection, within 9-11 minutes. The same amount of the bloods drawn during and after a given procedure was then tested against a like amount of acetylcholine. Where destruction followed a similar course, the enzymic concentration was held to be the same.

The sensitivity of this method is borne out by the following experiment, repeated many times in the course of our work. 0.05 c.c. of blood was added to 1 c.c. of acetylcholine solution (10 gammas). 0.1 c.c. of the mixture was injected at the end of 1 minute and every other minute thereafter. Complete destruction of acetylcholine was apparent at 7 minutes. 0.06 c.c. of blood produced complete destruction of the acetylcholine solution used at 5 minutes while each injection of this mixture produced a smaller drop in blood pressure than corresponding injections where 0.05 c.c. of blood was used. Likewise, definite differences were elicited when .045 c.c., .04 c.c., .035 c.c., and .03 c.c. of blood were used. (See Figs. 1, 2, 3 and 4).

Results: There is no difference in the rate at which bloods drawn before, during, and after constant injection

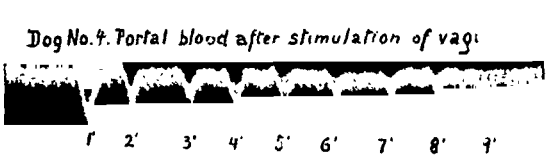

Fig. 6

*Supplied by Hoffmann-La Roche.

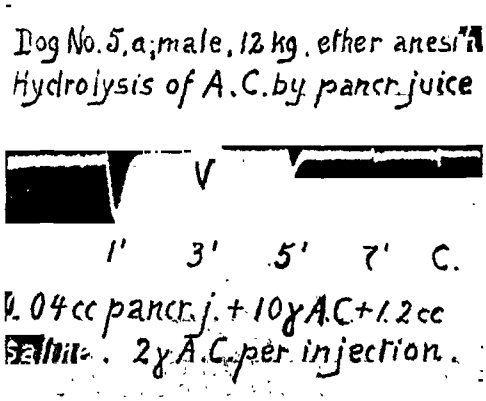

Fig. 7

of 375 to 600 mg. of acetylcholine produced hydrolysis of acetylcholine; this confirms previous work (9, 10).

B. Comparison of Bloods Drawn from Veins Leaving Various Organs (2 experiments). A few c.c.'s of blood were drawn within a few minutes from each of the following vessels: the femoral artery; femoral vein; renal vein; adrenal vein; vena cava; portal vein; splenic vein; and jugular vein of the test dog. These bloods were tested for their acetylcholine splitting power in the same manner as in the preceding experiment. This was done in order to determine whether any one organ might be the main source of choline-esterase. We realize, however, that small and possibly continuous production of esterase in one or even all organs (see Oppenheimer's theory of esterase being a waste product of cells) might not be detectable by our method.

Results: No difference was found in the rates at which these various bloods split acetylcholine.

C. Vagal Stimulation (2 experiments). Bloods were drawn from the above mentioned vessels before and after vigorous and prolonged faradic stimulation of the peripheral ends of the cut vagi in the neck.* These were tested in the usual way for their acetylcholine splitting power. The purpose of this experiment was to test the possible influence of vagus activity on the esterase concentration in the blood. (See Figs. 5 and 6).

Results: No difference was encountered in any of the bloods tested.

D. Cannulation of Pancreatic Duct (2 experiments).

As will be described below we found that pancreatic juice destroyed acetylcholine at fifteen times the rate of the blood. It was felt that should a secretion so rich in choline-esterase be diverted from the gut where it may be reabsorbed, a progressive decrease in the choline-esterase level of the blood might be the result; or that total extirpation of the pancreas as in the following experiment might result in a marked change in the blood esterase level. For this reason the following procedure was carried out. The pancreatic duct of a dog was cannulated and the pancreatic juice was collected. Fifteen c.c. of a secretin preparation was injected intravenously to stimulate flow of pancreatic juice. Blood samples were drawn from the femoral artery before and after collection of about 20 c.c. of pancreatic juice. These blood samples were tested against acetylcholine in the usual manner.

Results: No difference was found in the ability of these bloods to split acetylcholine.

E. Extirpation of the Pancreas (1 experiment).

Blood was drawn from a dog completely depancreatized one month previously and tested in the usual manner.

Result: There was no difference in the ability of this blood to destroy acetylcholine. Compared with that of normal dogs this blood was not lacking in choline esterase.

F. Reticulo-Endothelial "Blockade" (1 experiment).

A dog weighing 22 lbs. received intravenously in four days 500 c.c. of an 8% suspension of Higgins' India Ink in an attempt to block its reticulo-endothelial system. The spleen was removed, after which a sample of blood was drawn from the femoral artery. Then 100 c.c. of a 6% suspension of India Ink was injected into the femoral vein and constant injection of acetylcholine was begun. After 280 mg. of acetylcholine had been injected, a second sample of blood was drawn. These bloods were tested in the usual manner. The purpose of this experiment was to detect a possible influence of the reticulo-endothelial system on formation or destruction of esterase.

Results: No difference in the acetylcholine splitting power of these bloods were noted. Compared with the records of other dogs, there was no deficiency of esterase in the "blockaded" dog.

G. Devisceration (3 experiments).

The gut of the subject dog, from the abdominal esophagus to the lower rectum was removed, as was the spleen and pancreas. The hepatic artery and portal vein were ligated close to the liver. A sample of blood was drawn from the femoral artery after which constant injection of acetylcholine was begun. Over a period of about 3 hours from 430 to 500 mg. of acetylcholine was injected. Samples of blood were drawn during and after constant injection and these were tested for their acetylcholine splitting properties in the usual manner. This experiment was performed in order to eliminate possible effect of the liver, stomach and intestines on the formation or destruction of esterase.

Results: There was no difference in the acetylcholine splitting powers of these bloods.

II

In the course of our work we took the opportunity to test some as yet untested substances for their esterase content.

Tsuji (8) found esterase present in lymph. Plattner and Hintner (15) have reported the presence of esterase in the aqueous humour, while finding it absent in saliva, milk and urine. Vahlquist (5), Shaw (7), and Stedman (17), however, have been unable to corroberate these authors' findings of esterase in spinal fluid, using a more delicate test.

We have collected fresh pancreatic juice from dogs by cannulating the main pancreatic duct and have found that it is capable of destroying acetylcholine at about fifteen times the rate of blood. This action is entirely inhibited in the presence of 1:10,000 solution of eserine. (See Figs. 7 and 8).

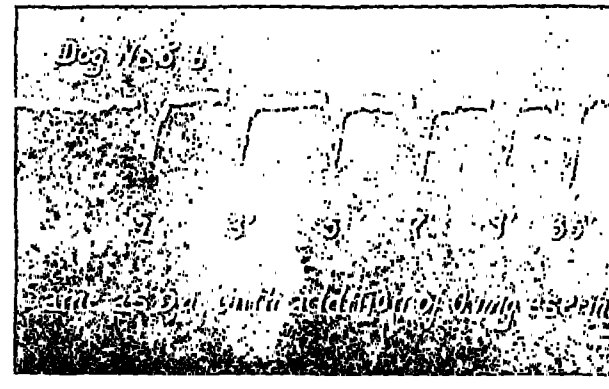

Fig. 8

*Harvard inductorium, 7 cm. coil distance, for 2 periods of 15 minutes each.

Blood free fluid from a congenital cerebellar cyst produced a rapid destruction of acetylcholine.

The urines of two nephritic patients, containing large amounts of albumin and globulin, were incapable of splitting acetylcholine. One might have expected that a kidney which is permeable to plasma proteins might also excrete esterase.

Blood-free ascites fluid produced a rapid destruction of acetylcholine.

Blood-free pus collected from the chest of a patient with empyema, was centrifuged and washed with saline. The precipitate was suspended in a small quantity of saline and tested for its acetylcholine splitting ability. It was entirely ineffective in hydrolysing acetylcholine over a period of one hour. The supernatant portion of the centrifuged pus, however, was able to split acetylcholine rapidly. A smear of the precipitate showed it to be made up almost entirely of polymorphonuclear leucocytes. Matthes (18) considers the activity of the choline-esterase of the blood to be "compatible with the action of an enzyme largely concentrated on the surface of the corpuscles," because the enzymatic activity of the cells is greater than that of the serum and also because, as Plattner and Hintner (15) have shown, swelling of cells increases their enzymatic action. Engelhart and Loewi (2) found that red cells and platelets were able to destroy acetylcholine. In the light of these findings it is interesting that pus cells apparently do not possess the choline-ester splitting property while the liquid portion of the pus with its cellular debris possesses this property to a marked extent. In spite of the high choline-esterase content of the pus, the enzyme did not become adsorbed to the cell surfaces.

SUMMARY AND CONCLUSIONS

1. Constant injection of acetylcholine, infinitely greater in quantity than that elaborated physiologically, produces no marked change in the esterase level of the blood, during approximately six hours of observation.

2. Extirpation of the spleen, pancreas, gut, liver and blocking of the reticulo-endothelial system resulted in no decrease in the esterase level of the blood during the period of observation.

3. Vigorous vagal stimulation had no effect on the esterase level of the blood.

4. Venous blood from various organs showed no differences, as tested by our method, in esterase content.

5. In the light of the above experiments it is not surprising that the esterase level shows only small variations in most normal and pathological conditions. It is felt that the esterase level of the blood is a rather immobile, unresponsive bulwark against an excess of acetylcholine in the blood.

6. Pancreatic juice has approximately fifteen times the acetylcholine splitting power of the blood. This ability is totally inhibited in the presence of eserine.

7. Ascitic fluid, fluid from a cerebellar cyst and the fluid portion of pus destroy acetylcholine.

8. Nephritic urine containing albumin and globulin, does not possess this ability, nor do washed pus cells.

Treatment of Pylorospasm with Digitalis: Report of Five Cases

By

EDWARD HOLLANDER, M.D.*
NEW YORK, NEW YORK

THERE is a striking similarity in the innervation of the heart and the stomach. We have evidence that there is a node on the lesser curvature near the cardia which acts as a gastric pacemaker analagous to the sinoauricular node in the heart. Impulses travel by a conductive system along the lesser curvature of the stomach similar to the auriculoventricular bundle of the heart (1).

Spastic motor disturbances in peptic ulcer may be due to abnormal impulses travelling along the conductive system of the stomach. Because of the known action of digitalis in depressing the impulses in the conductive fibres of the heart, the author (2) suggested the use of digitalis in the treatment of peptic ulcer, with the expectation, that if digitalis would have a similar action on the conductive system of the stomach, spastic phenomena would be relieved.

The present paper is a report of five cases of marked pylorospasm with six hour residue that were relieved by digitalis therapy. These cases presented a similar clinical picture and were treated in a uniform manner, so they will be discussed as a group. When first seen, these patients complained of constant midepigastric pressure or burning pains from two to eight weeks in duration. They had been under treatment with alkalies without relief. None of the patients vomited spontaneously but several of them found that forced vomiting was the only means of obtaining temporary relief. All complained of loss of appetite

*Gastro-enterologist, Manhattan State Hospital.
Submitted December 30, 1936.

and had limited their diet to liquids and dairy foods. When the cases were first examined by means of the Roentgen-ray the stomach was atonic and ptosed; peristalsis was absent or very weak and very little barium passed through the pylorus. At six hours the gastric residue was approximately one-half to two-thirds of the original gastric content. It was not possible to determine at that time whether the obstruction at the pylorus was organic or functional, although the lack of irregularity at the antrum favored the diagnosis of functional spasm.

Digitalis was administered by the rapid method of Eggleston, calculating two minums of the tincture to the pound of body weight. Only three-quarters of the calculated dose was given, for Gold and DeGraff (3) showed that the therapeutic effects of digitalis in the heart was obtained by doses short of producing toxic effects. The dose was divided into three equal parts at 8 a.m., 2 p.m. and 8 p.m. A maintenance dose of digitalis was prescribed for the following day: four drams of the tincture to four ounces of Elixir Aromaticum. A teaspoon diluted in one-quarter glass of water was taken after meals, three times a day. No change in the diet was made and no treatment other than the administration of digitalis was given. The patients were observed every day to detect any toxic effects from the digitalis but none developed. They reported moderate relief from symptoms after the first day and complete relief after the second or third day of the digitalis therapy. Because of the marked gastric retention originally present with consequent delay in the absorption of the digitalis, the Roentgen-ray examination was not repeated until the patients reported complete relief from symptoms. In three cases the barium meal was repeated at the end of the second day and in the other two cases at the end of the third day from the start of the treatment. The examination then showed a marked increase in the tone of the stomach causing an elevation in the position of the greater curvature. The peristaltic waves were active, increased both in their rate and depth and the pyloric sphincter was functioning. At the end of six hours the stomach was completely empty. An irregular duodenal cap was present in the five cases.

CONCLUSION

Five cases of pylorospasm with six hour residue were treated by oral digitalization.

Complete relief of the pylorospasm, both in subjective and in Roentgen-ray findings was obtained in two to three days.

The Influence of Large Doses of Vitamin D Administered Systemically and Locally on the Healing of Ulcers*

By

MAX BERG, M.D.
CHICAGO, ILLINOIS

SINCE it has been shown that large doses of vitamin D stimulate the metabolic rates in experimental animals (1), that it may stimulate the metabolic rates in children (2), and that an increase in the oxygen consumption occurs in the isolated muscle (3), we decided to study the influence of large doses of vitamin D in the form of viosterol administered both systemically and locally on the growth of granulation tissue. Tammann (4), working with rabbits administered simultaneously large doses of vitamin D by mouth and topically. He found that the uncovered skin ulcers in the vitamin D treated animals healed more slowly than similar controls, with degenerative changes occurring in the marginal region of the wounds giving them a bad appearance. Microscopically, many of the vessels were occluded due to a medial degeneration.

METHOD

On the backs of rabbits, circular ulcers were cut through the skin to the underlying fascia. The ulcers were cut 1 cm., 2 cm. and 5 cm. in diameter respectively in 3 groups, the 5 cm. group corresponding to those of Tammann. All of the ulcers were protected with a covering which was not in contact with the ulcer. Of the first group of animals with the 5 cm. ulcers, nine were fed viosterol,† 10,000 units per kilo, nine were untreated, six had the ulcers covered with equal amounts of viosterol (1,000,000 units per gram), and six were covered with equal amounts of non-irradiated ergosterol† in corn oil (2%) daily. Of the second group of rabbits with two ulcers 2 cm. in diameter, four had one of the ulcers covered with equal amounts of viosterol daily, and four had one of the ulcers covered with the non-irradiated ergosterol. Of the third group with ulcers 1 cm. in diameter six animals were given viosterol locally, six received the ergosterol in oil, and six were untreated.

RESULTS

Of the group of animals with the 5 cm. ulcers, those receiving viosterol by means of a stomach tube were healed in an average of 19 days with a range of variation of from 18 to 20 days. Those receiving the viosterol locally were healed in 17.6 days, with a range of 17 to 19 days, the animals receiving the non-irradiated ergosterol locally were healed in an average of 18.5 days, with a range of 17 to 20 days, while the group that was untreated was healed in 17 days, with a range of 15 to 19 days as shown in Table I. The ulcers of all of these animals were clean and the scabs firm.

*From the Department of Pathology and Bacteriology, College of Medicine, University of Illinois.

†The viosterol, and crystalline inactive ergosterol were generously provided through the courtesy of Mead Johnson & Co., Evansville, Ind.

TABLE I

Rabbits with 5 cm. ulcers

	Viosterol by mouth	Viosterol locally	Oil locally	Untreated
Average No. days required to heal.	19	17.6	18.5	17

The results of the second group of rabbits with the two cm. ulcers may be seen in Table II. The maximum variation in the number of days required to heal the ulcers was two.

The results of the third group with the ulcers 1 cm. in diameter may also be seen in Table II.

Microscopic sections taken 48 hours after the ulcers were made revealed a superficial layer of fibrin and blood cells intermingled, and beneath this a marked leukocytic infiltration with fibroblasts and newly formed capillaries. There was no demonstrable difference in the sections of any of the animals of the different groups. Sections of the healed ulcers were made and they revealed a dense connective tissue with well developed arterioles. Here again no demonstrable difference in the healed ulcers of the different groups were observed.

The animals were weighed before and after the experiment and they showed no loss in weight and did not appear dehydrated. Four of the animals died before the experiment was completed and one died the day after. Three of the deaths were in the group that was fed viosterol, one was in the untreated group, and one was in the group treated with the non-irradiated oil. In all of the cases, the cause of death was a pneumonia.

Thus, it may be seen, that in the group of animals that were fed viosterol by mouth the ulcers healed at about the same rate as the untreated ones, the average being two days slower (8%). The appearance of the ulcers both grossly and microscopically was similar to those untreated. No evidence of a stimulation of granulation tissue was observed, and the toxic effects previously described (4) were not found. The application of viosterol on the ulcers of various sizes revealed no significant differences in the rate of healing from those that were untreated. The animals receiving the non-irradiated ergosterol showed a rate of healing that closely approximated that of the animals treated with viosterol and the untreated group.

CONCLUSIONS

1. Large doses of vitamin D in the form of viosterol (1,000,00 units per gram) applied locally have no appreciable influence on the rate of healing and the character of ulcers in the rabbits.

TABLE II

		Animals receiving Viosterol on one ulcer		Animals receiving Non-irrad. oil on one ulcer		Prelim. untreated
		Viost.	Untreated	Oil	Untreated	
Ave. No. days required to heal.	Rabbits with 2 cm. ulcer.	15	14.6	16	15	11
	Rabbits with 1 cm. ulcer.	10	11.3	11	11	

2. Large doses of vitamin D by mouth produce no change in the character of the healing ulcers in the animals. The rate of healing was approximately the same as that of the controls.

3. Applications of non-irradiated ergosterol produced no appreciable changes in the rate of healing of ulcers in the rabbit.

The Factor of Spasm in the Etiology of Jejunal Ulcer*

By

G. B. FAULEY, M.D.

and

A. C. IVY, M.D.

CHICAGO, ILLINOIS

STEINBERG and Starr (1) have presented experimental evidence which indicates that spasm of the jejunal musculature is an important factor in the etiology of jejunal ulcer. Their experiment consisted of draining the duodenal secretions (pancreatic juice and bile) into the terminal ileum and of anastomosing the jejunum to the stomach. The jejunum, however, was stripped of its longitudinal and muscular coats (except that near the mesenteric border) for a distance of 10 cm. from the end-to-end gastrojejunal anastomosis (Fig. 1, A). They failed to observe the occurrence of ulcer in the stripped portion of the jejunum. In four of ten dogs so operated ulcers were present just distal to the point where the muscle had not been de-

* Physiology and Pharmacology, Northwestern hool, Chicago, Ill.

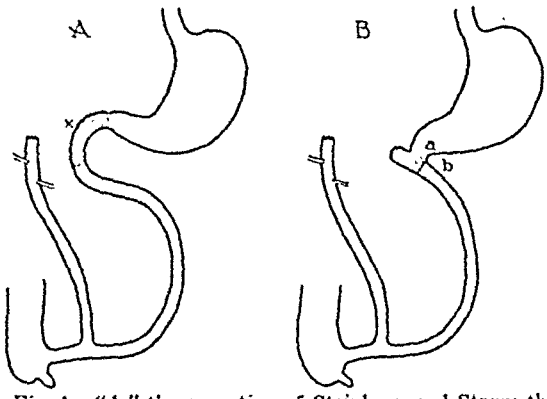

Fig. 1. "A," the operation of Steinberg and Starr; the portion marked "X" was stripped of three-fourths of its musculature. "B," our operation. Distance from "a" to "b," 3 cm.

nuded. This result, regardless of the fact that their ten animals survived the operation from only 7 to 76 days, was most interesting. We have slightly modified their operation and have extended their experiment to ascertain whether local muscular spasm in the jejunum is essential for the formation of jejunal ulcer.

METHOD

We performed the operation shown in Fig. 1, B, which differs from the Steinberg-Starr operation only in that we performed an end-to-side anastomosis. The longitudinal and circular musculature stripped readily and we were careful to remove the musculature surrounding three-fourths of the jejunum, leaving that adjacent to the mesentery intact. The stripping was done before the jejunum was incised longitudinally for the purpose of making the anastomosis. Further, our dogs were fed a special diet which we have shown previously (2) to maintain Mann-Williamson dogs in a better nutritional condition than the ordinary diet of meat, milk and bread. This diet consists essentially of cooked ground meat and cereal, milk, tomatoes and cod liver oil, corn syrup, raw ground liver and pancreas. This diet was fed twice daily in the amounts desired by each animal.

RESULTS

Control experiments: Twenty dogs were operated as shown in Fig. 1, B, except that the muscle was not denuded. They were fed the special diet. These dogs constituted the control group.

Ten of the animals survived from 9 to 17 weeks, only three dying with ulcer. Nine of the remainder survived from 20 to 58 weeks all having ulcer. One survived 82 weeks and did not develop ulcer. The average survival time of the 12 animals having ulcer was 26.7 weeks.

Experiments in which the jejunum was denuded of its musculature except for that one-fourth along the mysenteric border: Fifteen dogs were operated as shown in Fig. 1, B. They received the special diet. One of the fifteen developed a jejuno-duodenal anastomosis and survived for 76 weeks, and hence cannot be counted in this experimental series. Of the remaining 14 animals, thirteen died with ulcer at 10, 18, 14, 15, 26, 23, 36, 29, 78, 11, 34, 24, and 23 weeks. One animal which was anesthetized at 76 weeks did not have an ulcer. *The ulcer without an exception was located in the position of the jejunum stripped of its musculature or at the usual site,* and not where we expected it to be located, on the basis of the observations of Steinberg and Starr. The ulcers as a rule were large and very indurated. The base of the ulcer was usually not located at the site of the mesenteric border, and the ulcers perforated either on the anterior or posterior wall, although in some instances the adhesions were so marked as to render uncertain the exact location of the base of the ulcer in regard to the mesentery. The average survival time of the 13 animals having ulcer was 26 weeks.

DISCUSSION

It is reasonable to believe hypothetically that local muscular spasm might be an important predisposing factor for the development of ulcer. It is well known that spasm of the pyloric antrum may cause hemorrhages into the mucosa which result in hemorrhagic erosions. We had hoped that by using our special diet, which delays the onset of perforation and lethal hemorrhage, and by ruling out the factor of spasm by denuding the musculature, as in the experiments of Steinberg and Starr, ulcers would not develop. This hope was not realized. Neither was the time of onset of perforation and lethal hemorrhage significantly effected, because the average survival time of the control animals having ulcer was 26.7 weeks and that of the animals with a "denuded" jejunum was 26 weeks.

Our findings do not necessarily annul those of Steinberg and Starr, because we deliberately performed an end-to-side anastomosis and fed a diet which delays the onset of perforation and lethal hemorrhage. An end-to-side anastomosis would tend to reduce the factor of spasm because the jejunum is sectioned along the border opposite its mesentery, a point of obvious surgical import. A diet which retards the development of ulcer might give the local mechanisms in the jejunum time to compensate for and to reduce the factor of spasm. The animals of Steinberg and Starr lived a very short time as compared to the survival of our animals. Thus, local muscular spasm may be a factor which contributed to the more rapid development of an ulcer in its early stages. However, it is not an essential factor for the development of jejunal ulcer after gastrojejunostomy.

CONCLUSION

Local muscular spasm in the jejunum is not an essential factor for the development of jejunal ulcer after gastrojejunostomy.

Glucose Tolerance as a Diagnostic Aid in Jaundice
III. Toxic Hepatitis*

By

HARRY G. JACOBI, M.D.†
NEW YORK, NEW YORK

THE syndrome resulting from toxic changes in the liver has been variously described under such titles as Acute Catharrhal Jaundice, Toxic (Arsphenamine, Cinchophen) Jaundice, Acute Infectious Jaundice and Acute Yellow Atrophy. Such titles place undue emphasis upon the outstanding symptom of jaundice, rather than upon the marked underlying pathological lesion. A more comprehensive appreciation of this very important disease entity would be obtained by including all these cases under an appropriate common title, such as Toxic Hepatitis. This heading would therefore include all the so-called non-obstructive or non-surgical cases of jaundice.

Experimental observations on liver damage and repair constitute an important basis for comparison with corresponding clinical conditions and while not all these can be exactly duplicated in the experimental animal, the value of such observations nevertheless, cannot be overemphasized. There are three parts into which such experimental work may be divided. First: The accurate observation of the reaction in the liver, to the introduction of toxic substances. Second: The process of repair that follows this period of reaction. Third: Those factors which help or retard this reparative process.

From the clinical standpoint, there are two important facts which must be added to the above. First: The accurate means of detecting Toxic Hepatitis cases from other conditions associated with jaundice, and Second: The best method available to effectively treat the condition.

PATHOLOGY

Before describing the changes observed in the liver of experimental animals, following the administration of various toxins, it might be well to mention briefly some very important structural features of the liver itself. As is well known, the capillaries that are formed, after the union of the portal and hepatic terminals, run in part directly to the efferent or central vein of the liver lobule or to that of the adjoining one. (Fig. 1). It has been demonstrated that the portal vein and hepatic artery may be ligated separately without producing any serious effect, but if the smaller branches of the portal vein are occluded where the hepatic arterioles join them, the blood supply is cut off from the liver cells and they die. The bile capillaries are bounded on all sides by the liver cells forming the continuation of their lumen. The epithelium of these bile ducts is therefore of the same type as the liver cell but not so highly specialized. Furthermore, it must be emphasized that the elements which make up the liver tissue are not all equally resistant to toxic agents. The more highly specialized liver cells for example, are killed first by the action of toxins, leaving the less delicate bile-duct epithelium intact and capable of growth. The connective tissue frame-work and blood vessels are even more resistant to such toxic irritants.

The method commonly employed to produce diffuse injury of the hepatic parenchyma experimentally, with as little damage as possible to the other organs, has been by means of the administration of phosphorus and chloroform. The hepatic factor in such toxic processes seems quite outstanding and as Williamson and Mann (1) have emphasized, the liver is found to be the most seriously damaged organ both histologically and physiologically. Mosiman and Whipple (2) in their work along these lines showed that phosphorus attacks chiefly the cell protoplasm. Opie and Alford (3) found that the lesions produced by moderate phosphorus poisoning consist of fatty degenerative changes. In the early stages these lesions are confined to the centre of the lobules, while later they are most conspicuous near the portal spaces. In the severe types of poisoning with phosphorus, marked areas of coagulation necrosis are produced which have a tendency to involve the peripheral portion of the lobules. Whipple and Sperry (4) followed experimentally the lesions in various organs, caused by chloroform administration and gave an excellent histologic picture of the liver injury and repair.

In the laboratory animal, typical chloroform necrosis effects the centers of the liver lobules, and this damage can be definitely demonstrated six to ten hours after the administration of the drug. The dead areas usually appear hyaline and quite homogenous in from twenty-four to forty-eight hours. Wandering cells then make their appearance and aid the tissue fer-

ments in removing the necrotic mass. In cases of recovery, this process occurs between the second and fifth days. During this process of dissolution, the neighboring intact liver cells begin to proliferate. Numerous mitotic figures are observed with the extension of cell strands into the stroma, which was recently filled with dead material. Even under the most favorable conditions, there is a period between the removal of the debris, and final repair, when a certain amount of unfilled stroma is to be seen surrounding the central vein. In an acute case of delayed chloroform poisoning, if death occurs within two or three days, the liver will be enlarged and yellow and many of the cells will show distention with fat globules. If death occurs in about a week or so, the liver will be much shrunken in size owing to the absorption of the cells which previously showed fatty distention. In both of these cases the liver cells must have undergone death from the toxic effects to which they had been exposed. It has been estimated that a liver necrosis involving practically 50% of all the liver parenchyma will be usually completely repaired in from seven to nine days, in the laboratory animal surviving such damage.

These above mentioned poisonous agents also impair the excretory power of the liver cells for removing bile from the blood, with the consequent increase in the concentration of the circulating bile pigments. This increase in circulating bile pigments usually results from some intrahepatic damage and functional derangement, whereby these bile pigments from the endothelial cells are unable to enter the polygonal cells and instead pass directly into the hepatic vein, and thence into the general circulation, where they continue to accumulate. A second mechanism that must be taken into consideration is the possibility of an excessive blood destruction occurring in the course of a toxic hepatitis. As a result of this, more bilirubin is formed in the reticulo-endothelial cells than can be absorbed by the liver cells. This excess of bile pigments passes directly into the hepatic veins and accumulates in the circulating blood. The degree of im-

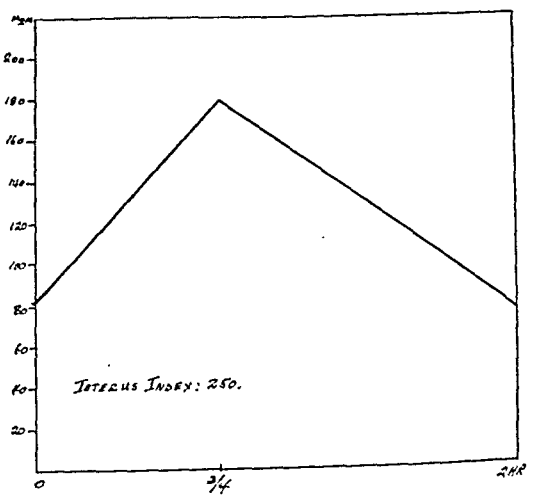
pairment in this function of the liver can be definitely determined by means of the icterus index (5).

HEPATIC GLYCOGEN AND BLOOD SUGAR

The presence of glycogen and glucose in the liver cells, seems to increase their power of resistance to all toxic agents. This assumption has been definitely confirmed by the work of Whipple and Sperry (4) and Davis (6). Graham (7) found that the resistance of pups to late chloroform poisoning is due to their increased hepatic glycogen. This resistance could be destroyed by starving the pups. On the other hand adult dogs were found to have a lessened susceptibility to poisons after a period of high carbohydrate feeding. Likewise Davis and Whipple (8) found that starved animals are very susceptible to liver injury from chloroform. Adequate sugar administration or the intake of diets rich in carbohydrates for several days preceding the chloroform anesthesia, exerts a marked protective action against liver injury. They therefore suggested this as a method of treatment, in cases of toxic liver damage.

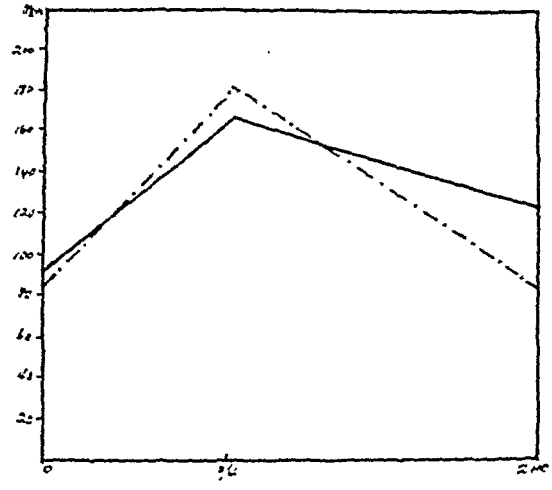
In patients with hepatic disease, Althausen and Thoenes (9) noted that after receiving 20 units of insulin and 50 gm. of dextrose orally there was usually observed an initial rise in the blood sugar followed by an abrupt decline. In some cases, no initial rise was observed, but an uninterrupted diminution of the blood sugar level occurred. Both these type curves ended in marked hypoglycemia. In animals with experimentally induced liver damage, these investigators (10) found that the first functional deficiency of the liver to be observed following toxic injury, was a failure on the part of this organ to maintain the normal blood sugar level, and in the last stages of poisoning, blood sugar curves ending in hypoglycemia were rather typical, after the modified dextrose tolerance test. Unfortunately, however, no icterus index determinations were made in any of these animal experiments. Meulengracht (11) likewise reports that in cases of acute hepatitis, accompanied by various degrees of icterus, the fasting blood sugar value was found to be below the normal figure. In three cases of severe hepatitis terminating in death with features of acute yellow atrophy, he found very low fasting blood sugars, the lowest being 33 mgm. per 100 c.c. of blood.



In a previous communication (12) I reported a group of jaundice patients, showing their response to the administration of glucose by means of the ordinary sugar tolerance test. The toxic cases showed a fairly typical reaction whereby the blood sugar at the end of the two hour period always returned to normal levels, and showed very little increase in the blood sugar in spite of tremendous doses of glucose administered. This response was not obtained in cases of obstructive jaundice.

BILE AND GLYCOGEN FORMATION IN THE LIVER

Very little work has been done on the exact relationship existing between the glycogen formation and the bile formation function of the liver. Forsgren's (13) observations may be mentioned in this connection as warranting further corroborative investigation. He concluded from his experimental work on rabbits, that an antagonism exists in the liver cells between bile formation and glycogen formation. These two processes appear unable under normal conditions, to simultaneously attain a maximum. He also found that within the periphery of the lobule, the liver cells are more often engaged in the formation of bile, while within the central zones they are more engaged in the formation of glycogen. Both these processes of bile and glycogen formation were found to proceed in definite periodic cycles during the twenty-four hour period. Such observations are of extreme importance in their bearing on the behavior of glucose administered in the presence of jaundice.



GALL BLADDER VISUALIZATION IN TOXIC JAUNDICE

The use of tetraiodophenolphthalein as a means of testing the physiological capacity of the excretory function of the liver in the presence of jaundice has not been sufficiently stressed. We feel that this procedure has not received the attention that it deserves

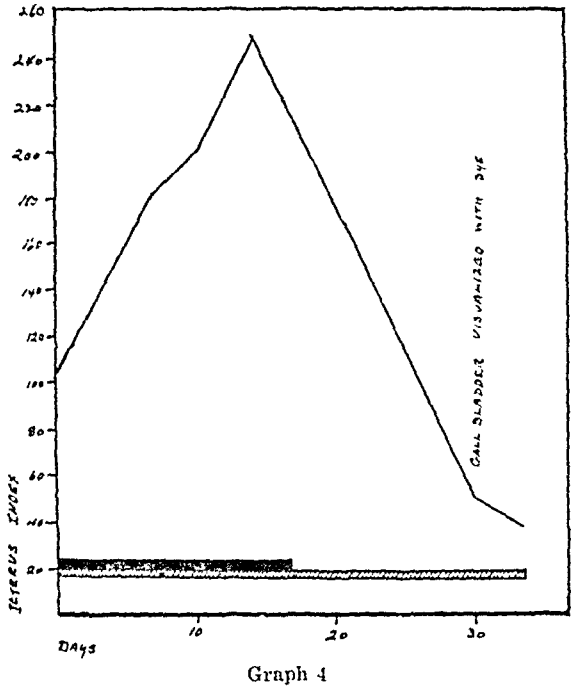
Graph 2

Case 44210. Age 42. Sex, Female. Gall bladder visualized at icterus of 58. Sugar tolerance curve.

Graph 3

Case A. D. History No. 44210. Age 42 years. ——— Date 1 31 35. Icterus Index 105. —.—.— Date 3 12 35. Icterus Index 42. Sugar tolerance curves.

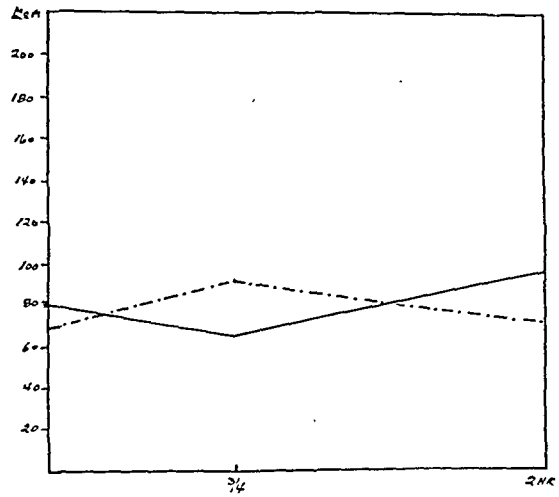
as a diagnostic aid in jaundice. Considerable aloofness has been shown to the employment of gall bladder visualization in the presence of jaundice. This attitude probably originated with the report of early studies on the intravenous method of administration of the dye when harmful toxic reactions were reported, due to the impurities present when the dye was first introduced and also to the intravenous method of administration. In 1930, Rudisill (14) reported the intravenous use of the dye for gall bladder visualization in a series of eight cases of infectious jaundice, without any harmful effects. In seven of these cases he was successful in obtaining visualization. The exact degree of icterus in these cases is not given. Foley (15) reported a series of 29 cases of jaundice in whom gall bladder visualization by the oral method was performed. Of this entire group 16 were cases of toxic or non-obstructive jaundice and 13 were surgical or obstructive jaundice cases. In the obstructive jaundice cases no visualization was obtained. In the toxic group 11 of them showed a gall bladder shadow after the oral administration of the dye. The highest icterus index at which such visualization was obtained in this group of toxic cases was 90. Foley further states that he has been in the habit of doing cholecystography in cases of jaundice with the understanding that a negative shadow is of no significance either way. A positive shadow, however, in the presence of jaundice indicates the normal functioning of the extra-hepatic bile ducts and therefore establishes the cause of the icterus as due to some intra-hepatic pathology.



Foley's observations agree with our findings (12) where we obtained gall bladder visualization by means of the oral method in 7 out of 8 cases of toxic jaundice. The highest icterus index at which successful visualization was obtained in these 7 cases was 66.

PROCEDURE

The fasting blood sugar and icterus index determinations are made on all jaundice patients, shortly after admission to the hospital. A sugar tolerance test, using 100 grams of glucose is performed. While half hourly determinations of the blood sugar may be made, we have found that the 45 minute and 2 hour observations furnished the necessary information. Cases that show a return of the blood sugar to normal at the end of the two hour period with blood sugar curves corresponding to those shown in Graph 1 or Graph 2, receive 250 Gm. of glucose orally and a continuous intravenous drip of 10 to 15% glucose solution. Icterus index determinations are made every other day. After about 7 or 8 days of this intensive glucose therapy, gall bladder visualization by means of the oral method is attempted.



OBSERVATIONS

Our present report is based upon a study of twenty-five cases. There are 20 males and 5 females in the group (Chart 1). The ages vary from 20 to 59 years. The icterus index varies from 13.5 to 250. All the cases responded to the glucose tolerance test in one of the two following ways: The flat curve, similar to that shown in Graph 1, where the rise in the blood sugar is very slight throughout the period following the intake of the glucose. The second type reveals a low fasting blood sugar followed by an early high rise and a subsequent fall to the normal level at the end of the 2 hour period. An example of this type of curve is shown in Graph 2. The first type of curve is obtained in those cases of toxic hepatitis where the toxicity is quite severe and where the icterus index is high, while the second type which is the usual normal sugar tolerance curve, is seen in cases where the icterus index is below 40 and where not much toxicity is present. The important feature of both those curves is that the blood sugar at the end of the two hour period returns to the normal level. The fasting blood sugar level is rarely elevated in these cases and seems to bear a direct relationship to the severity and duration of the toxic process. As this process increases in

Graph 4

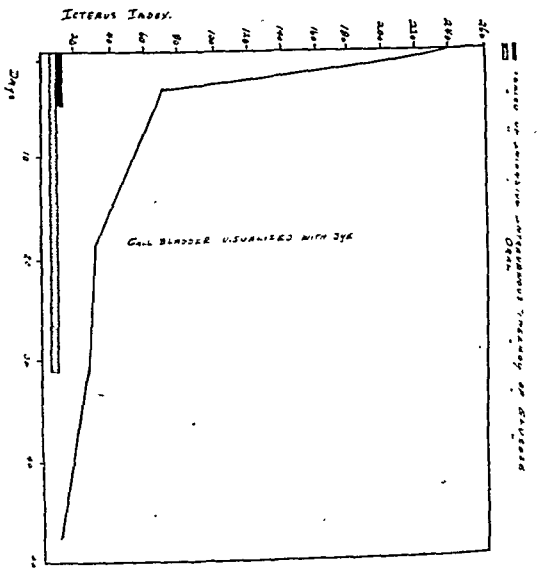
Graph 5

Case K. C. History No. 52139. Age 34 years. ——— Date 5/6/36. Icterus Index 227. —.—.— Date 5/18/36. Icterus Index 33. Sugar tolerance curves.

severity, the fasting blood sugar values become lower and some of our lowest figures are noted in the fatal cases that develop into acute yellow atrophy. The lowest fasting blood sugar for the group is 50 milligrams per 100 cubic centimeters of blood and highest 99 milligrams per 100 cubic centimeters of blood, with an average of 78 milligrams per 100 cubic centimeters of blood. In 9 of the cases in this group, gall bladder visualization was attempted and was successful in 8 of them. The highest icterus index at which successful gall bladder visualization has been obtained in these 8 cases is 66. The icterus index in the unsuccessful case is 100. There are six deaths in the group. In five of these cases post-mortem examination was made. Four of the cases were operated upon as the possibility of an obstructive type of jaundice was considered as very likely. Two of these operative cases resulted in death. One case was diagnosed by the operating surgeon as an inoperable carcinoma of the head of the pancreas. This patient died and post-mortem examination failed to reveal the carcinoma but showed the jaundice to be due to an Acute Yellow Atrophy.



We have selected four cases for detailed report, in order to point out some of the more important features of this group. Of these four cases two made complete recoveries and in the other two where death occurred complete post-mortem studies have enabled us to correlate such findings with our clinical and laboratory data.

CASE REPORTS

Case 1: A. D. Hist. No. 44210. Age 42 years, was admitted to the hospital on Jan. 30, 1935, complaining of jaundice and abdominal distress of several days duration. The patient had only recently, 12/14/34, been operated upon in the Gynecological Service of the hospital for a bilateral tubo-ovarian abscess. She had had a rather stormy convalescence, and was discharged on 1/13/35 in good condition. For the first ten days of her stay at home the patient continued to feel well. On the tenth day, however, she noticed that her eyes were yellow, and that she had a bad taste in her mouth. Her appetite was fair. There was some abdominal distress and slight pain in the right upper quadrant. There was no history of any upper respiratory infection. The only other significant feature in her past history was the fact that one year previously she had received quite a number of intramuscular injections for some "blood condition."

Physical examination on admission reveals a well developed and well nourished female who is markedly jaundiced. She has considerable dental caries and her mouth hygiene is quite bad. The chest is emphysematous in shape, no abnormal findings are present. The heart is negative. The abdomen is distended and the liver felt about one finger breadth below the costal margin. Spleen is not felt. Knee jerks present. Temperature is 99.6. Pulse 70. Respiration 22. The icterus index on admission is 105. The glucose tolerance test performed on 1/31/35 shows fasting blood sugar of 86 mgm. per 100 c.c. of blood. Forty-five minute specimen is 166 mgm. and the two hour specimen, 122 mgm. per 100 c.c. of blood. In other words, it shows a typical non-obstructive or toxic curve (Graph 3). The patient is therefore immediately placed upon the high carbohydrate regime with glucose therapy intravenously, and also by means of the rectal drip. On Feb. 3, 1935, three days after admission, the patient shows a marked rise in the temperature to 102.2 and appears very toxic. On 2/6/35 the icterus index is 181 and the patient complains of a good deal of nausea and vomiting and appears much more toxic and considerably worse than at the time of admission. On 2/9/35 the icterus index is 200 and by 2/15/35 it is 250 (Graph 4).

Several of the physicians in attendance are rather inclined to the idea that this is perhaps a case of common duct obstruction that should be operated upon. We are quite determined, however, to continue with the therapy above outlined especially after a repeat sugar tolerance test again shows a non-obstructive curve similar to the first one (Graph 3). The flat plate of the abdomen is negative. On 2/21/35 the patient shows a marked improvement and the icterus index is down to 166. This improvement on the part of the patient continues and so by 3/4/35 her icterus index is 58. At this point an attempt is made at the visualization of the gall bladder by the oral method (Fig. 2). An excellent gall bladder shadow is obtained in this case with an icterus index of 58. On March 12, 1935, the sugar tolerance test is repeated and

Graph 6

Case K. C. History No. 52139. Age 34 years. Sex, Male. Icterus index curve.

still found to be of the non-obstructive type (Graph 3). The patient left the hospital completely cured.

Case 2: K. C. Hist. No. 52139. Age 34 years, was admitted to the hospital on May 6, 1936, with the complaints of jaundice and severe itching of four weeks duration. Patient related that about five weeks previously he had been on a drinking spree which lasted all night. Following this he developed an upper respiratory infection which lasted for about 4 to 5 days. He then began to have nausea, vomiting, and gaseous distention for about two or three days. By this time he was definitely icteric and this together with his pruritis have been increasing since then. The stools were clay colored, and the urine dark red in color. There was a loss of 24 pounds in weight during the five week period. There was no history of drug ingestion, or of any intravenous therapy. The patient is employed as a salesman. There is nothing of any significance in his past or personal histories.

Physical examination reveals a well developed and well nourished young man who is markedly jaundiced. The temperature is 99.2, pulse 90, respiration 20 and blood pressure 136/80. There is marked evidence of scratching over the entire body. Patient is mentally alert. Mouth and throat are negative. The heart and lungs are negative. The abdomen shows the liver palpable, about three fingers breadth below the costal margin. Spleen is not palpable. No tenderness and no edema are present. Reflexes are active. Flat plate of the abdomen fails to reveal any evidence of calculus. The icterus index on admission is 227 and the glucose tolerance test shows fasting blood sugar of 81 mgm. per 100 c.c. of blood and 66 mgm. and 97 mgm. at the 45 minute and 2 hour period after the ingestion of the 100 gm. of glucose (Graph 5). The Wassermann test is negative. No diagnostic aid is obtained from the galactose tolerance test or the determination of cholesterol or cholesterol esters. The patient is immediately given high carbohydrate intake and 15% glucose intravenously in the form of a continuous drip with the arm put up in a supporting cast and a cannula inserted into the vein. The patient receives about 1500 c.c. during the 24 hour period in this way. On the fourth day of this intensive therapy, the icterus index is down to 71. On 5/18/36 the icterus index is further reduced to 66, and on 5/23/36 it is down to 33 (Graph 6). At this time the sugar tolerance test is repeated and shows 71 mgm., 92 mgm. and 74 mgm. for the fasting, 45 minute and 2 hour specimens respectively (Graph 5). The oral Graham test is performed at about this time with an excellent shadow obtained (Fig. 3). The patient is discharged from the hospital on June 26, 1936, with his icterus index down from 227 to 10 (Graph 6).

At a follow up clinic on Oct. 25, 1936, the patient reported that he was feeling perfectly well.

Case 3: (H. N. 44071). Female, 50 years old, who was admitted to the hospital on Nov. 7, 1934, with the history that six weeks previously she consulted a physician because of painful and swollen joints. These pains had been increasing in severity since their onset one year ago. Her doctor gave her 18 intravenous injections of some salicylate preparation, supposedly manufactured by some drug manufacturer and also a certain preparation of his own. The exact nature of these injections could not be definitely determined. Three weeks prior to admission she developed nausea, vomiting and jaundice. She has gradually become weaker and three days before admission she developed a temperature and gave evidence of some toxicity, as manifested by mental confusion, and nervousness.

The only other significant feature in her history was the fact that five years previously she underwent a series of injections for varicose veins, following which she became quite ill, and developed jaundice. These symptoms cleared, however, at the end of two weeks.

Examination of the patient reveals a rather obese middle aged white female who is very restless and somewhat irrational. Pulse is 124. Respiration 18. Temperature 101.6. Marked jaundice is noted of the skin and sclera. Lungs and heart do not show any abnormal findings. The abdomen is distended and the liver palpable two finger breadths below the costal margin. The spleen is not felt, the icterus index is 110 and the sugar tolerance curve reveals, fasting specimen of 50 mgm. blood sugar per 100 c.c. of blood. The 45 minute specimen is 88 mgm. and the two hour specimen 84 mgm. This curve is the flat type, similar to that shown in Graph 1. The diagnosis of a severe toxic jaundice is therefore made and intensive intravenous glucose therapy instituted. The patient's condition becomes progressively worse, and death occurs only three days after admission to the hospital. Post-mortem examination was obtained, and we shall of course limit our findings to the pathology of the liver. This is found greatly diminished in size, greenish in color, with intermittant yellow and hemorrhagic areas. The gall bladder is distended with approximately a dozen large facetted stones. No stones are found in the common or cystic duct. The liver, on removal, has a jelly-like consistency and on section shows the same yellowish and hemorrhagic areas throughout its entire substance. Microscopically there is noted a marked degree of granular degeneration involving practically all of the liver cells. The liver architecture and cells are completely destroyed, and necrotic. A diffuse leucotyic infiltration is noticed throughout.

Case 4: (H. N. 36566). Male, 42 years old, who was admitted to the hospital with the history that 2 weeks previously, he had a sore-throat, which lasted only for about 2 to 3 days. Following this the patient felt very weak and languid and had marked anorexia. Shortly after this a friend of the patient's noticed that he was jaundiced and this continued to increase in intensity up to the time of admission. There was some slight epigastric discomfort especially on walking. At about the time that the jaundice was discovered the patient noticed that his stools were clay colored and his urine dark reddish in color. There was no history of a previous attack of jaundice. There was nothing significant in the past history. The patient was married 12 years, wife was living and well. There were no children. On admission to the hospital the patient shows a pulse of 76, respiration 20 and temperature 99.4. He is a well developed and well nourished white male, who does not appear acutely ill. He is markedly icteric. There is a marked pyorrhoea of the gums and three unextracted roots are present in the upper jaw. These show considerable infection around them. The tonsils are cryptic and the pharynx markedly reddened. There is an enlarged gland present at the angle of the left jaw. The lungs are negative. The heart is slightly enlarged, with a soft systolic murmur present over the precordium. The abdomen is soft. The spleen is slightly enlarged to precussion and the liver is felt about two finger breadths below the costal margin. The blood Wassermann reaction is negative. X-ray confirms the presence of the unextracted roots, with apical infection present in the upper left lateral and bicuspid and upper right lateral roots. The icterus index is 87.5 and the glucose tolerance curve shows a fasting blood sugar of 84 mgm. per 100 c.c. of blood. The 45 minute and 2 hour specimens are 92 mgm. and 74 mgm. respectively.

Intensive glucose therapy orally and intravenously is instituted but in spite of this on Feb. 13, 1933, five days after admission, the icterus index has increased to 96, and the patient is beginning to have a septic temperature, with a markedly reddened throat. A blood culture taken on this day, shows a positive hemolytic streptococcus growth. The patient continues to appear very toxic and drowsy and on Feb. 20, 1933, the icterus index is 200. The intensive

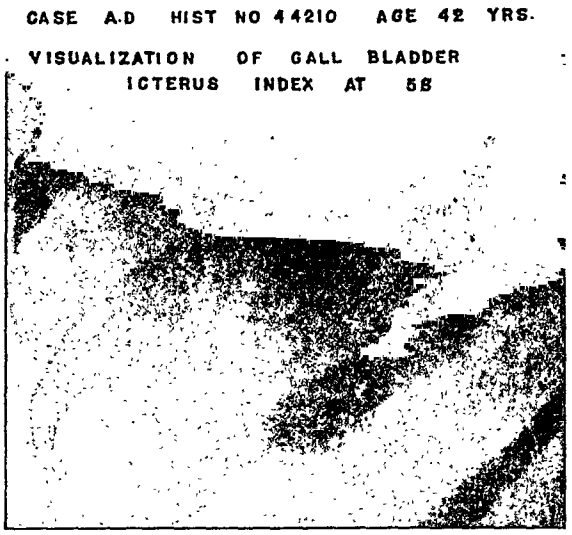


Fig. 2

therapy however is still continued. Two days later the temperature is normal, and the icterus index on Feb. 24, 1933, is down to 110. The patient appears much brighter and not at all toxic. A check on the blood culture on Feb. 16, 1933, reveals a sterile result. Feb. 26, 1933, the patient develops a large area of erythema on the back with a new rise in temperature and marked toxicity. On March 21, the icterus index is up again to 200 and the glucose tolerance test shows a fasting blood sugar of 74 mgm. and a 45 minute and 2 hour specimen of 78 mgm. and 60 mgm. respectively. The patient continues to grow steadily worse in spite of intensive intravenous and oral glucose therapy. The icterus index on March 7 is still 200 and on March 12 is the same. The sugar tolerance test on this day shows a fasting blood sugar of only 66 mgm. and a 45 minute and 2 hour specimen of 68 mgm. and 55 mgm. respectively. The patient continues to grow worse and expires.

Post-mortem: Examination reveals a small liver with scattered areas of greenish yellow markings throughout the organ. Microscopically there is seen a large number of liver cells completely destroyed and an apparent as well as a real cirrhosis due to the collapse of the stroma and an increase in the fibrous tissue. Throughout the sections there are found degenerating liver cells, serum, red blood corpuscles and inflammatory cells of all types. These inflammatory cells often form small collections in the stroma and the remaining liver cells.

DISCUSSION

Case 1 illustrates very decidedly the advantage of relying upon the glucose tolerance test, even in view of the fact that the patient's icterus continued to mount after admission to the hospital and after the intensive glucose therapy had been instituted. Some men even felt that surgical intervention should be undertaken. The galactose tolerance test, blood cholesterol and cholesterol esther determinations were of no value here. The flat plate of the abdomen was negative. It was really the intensive glucose therapy, intravenously, orally and by rectal drip that caused the marked improvement in this case. The visualization of the gall bladder was obtained with an icterus index of 58. This agrees with the results of Rudisill and Foley with similar experiences in cases of toxic jaundice.

Case 2 shows quite dramatically the excellent response obtained in these toxic hepatitis cases to the intensive administration of glucose intravenously. This patient was kept in bed and a cast made in order to immobilize his arm which contained a cannula sutured into the vein. The solution used was 15% glucose in Ringer's solution and of this the patient received between 1000 and 1500 c.c. during the 24 hour period, as an intravenous drip. How extremely effective this method of treatment is can be judged by the marked reduction of the icterus index from 227 on May 7, 1936, to 71 on May 14, 1936. Such results certainly warrant the advocating of this intensive method of glucose administration in all these toxic hepatitis cases with marked jaundice.

Case 3 shows a rather severe toxic hepatitis caused apparently by some preparation used intravenously for the relief of arthritic pains, probably cinchophen. The fact that this patient developed jaundice five years previously, following injections for varicose veins should have suggested to the attending physician, the susceptibility of the liver to damage, from the intravenous use of cinchophen. The sugar tolerance test on admission showed a very low fasting value of 50 mgm. per 100 c.c. of blood. The 45 minute and 2 hour specimens of 88 mgm. and 84 mgm. respectively likewise showed very little rise to the ingestion of the glucose. This curve is of the flat variety which in our experience denotes a toxic involvement of the liver of rather marked severity. The intensive glucose administration intravenously was of no help in this rather pronounced and advanced toxic lesion. It is of interest to note that the gall bladder contained about a dozen facetted stones. Mention is made of this fact because of the incorrect inference that could be drawn by a surgeon, operating upon a patient similar to this one and finding stones in the gall bladder. The natural conclusion would be to consider the case as one of obstructive jaundice. The glucose tolerance test appears to have given the more correct understanding of the underlying lesion.

Case 4 shows the course of a severe infection resulting in serious liver damage. The patient showed a typical non-obstructive sugar tolerance curve of the flat type. Under intensive oral and intravenous glucose therapy the patient began to show signs of improvement as evidenced by the drop in the temperature and also a reduction in the icterus index from 200 to 110. A few days later, however, a second infection (erysipelas) set in with a return of the icterus index to 200 and accompanied by a return of the marked toxic symptoms. This infection was apparently more than could be handled by this patient and he finally succumbed to it. The fasting blood sugars of the two subsequent sugar tolerance curves was 74 mgm. and 66 mgm. respectively. This decrease in the fasting blood sugar has been recognized as a bad prognostic sign in these severe toxic lesions of the liver.

From the available experimental and clinical data that has been presented one would certainly be justified in making the statement that glucose plays a very important role in toxic hepatitis. An attempt has been made here to utilize this reaction to glucose on the part of such patients, both from the diagnostic and therapeutic view points.

Various methods have been advocated for the differentiation of the so-called toxic from the obstructive

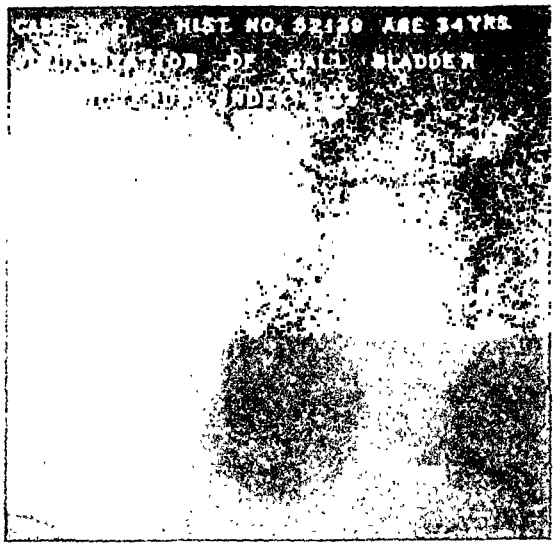

Fig. 3

cases of jaundice. These have included such determinations as the van den Berg, the galactose tolerance test, the study of uribilin, plasma cholesterol, cholesterol esters, etc. All of these, however, have been found wanting because of the variability in the results obtained. Thus in 1906, Bauer (16) attempted to utilize his galactose tolerance test as a means of identifying cases of toxic jaundice. Subsequent work has shown, however, that this claim is entirely too enthusiastic and oftimes misleading. Banks, Sprague and Snell (17) in a careful evaluation of this procedure arrived at the conclusion that it cannot be relied upon solely as a diagnostic procedure to distinguish between toxic and obstructive jaundice. In a previous communication (12) we have shown that such cases of toxic hepatitis with jaundice show certain characteristic blood sugar responses to the oral administration of glucose and that many of these cases that were previously subjected to operative procedures could be spared this additional strain if proper classification of these cases is made. Without entering into any theoretical explanation as to the exact mechanism which is involved in this reaction, we merely wish to stress our observation that whenever a case of jaundice gives a sugar tolerance curve, similar to that of Graph 1 or 2, the underlying pathology of the jaundice is due to toxic or non-obstructive causes and the intensive administration of glucose both orally and intravenously is definitely indicated. In such cases there should be no hesitancy to cut down on the vein in order to insure a regular and constant flow of glucose into the circulation. The arm should be immobilized by the application of a cast. The fact that such cases continue to show an increase in the icterus index even after the glucose therapy has been instituted for several days often causes unnecessary uneasiness and haste in advocating an exploratory operation. Such hasty action should be avoided and will help materially to diminish the mortality rate in the condition.

Our post-mortem studies have also brought out the fact quite clearly that the presence of calculi in the gall bladder is no definite proof that the existing jaundice is due to mechanical obstruction for we have on several occasions found calculi in the gall bladder and still definite pathological findings in the liver indicating an acute yellow atrophy, as the cause of the condition.

It also appears that the excretion of tetraiodophenolphthalein is closely associated with glucose assimulation in the body. Thus Antonucci (18) has shown that the gall bladder may be visualized more rapidly when large doses of glucose are administered. Stewart and Illick (19) also found that the excretion of dye by the liver is facilitated by the simultaneous administration of sugar, and have utilized this principle by giving sugar by mouth along with the oral administration of the dye to obtain a maximum of liver excretion.

Such visualization of the gall bladder in the presence of jaundice has in our experience been present only in the cases of toxic jaundice. We therefore agree with the opinion expressed by Foley, that the absence of a shadow is of no value at all, but the presence of one confirms the existence of a non-obstructive jaundice.

SUMMARY AND CONCLUSIONS

1. Toxic hepatitis cases show a marked capacity for utilizing large amounts of glucose, regardless of the mode of administration.

2. These cases react in a fairly characteristic manner to the usual glucose tolerance test by showing blood sugar curves similar to those seen in Graph 1 or Graph 2, the characteristic feature of which is a return to the normal level at the end of the two hour period.

3. As a rule, the more severe cases show a reaction similar to that seen in Graph 1.

4. No definite relationship has been found to exist between the degree of icterus and the severity of the toxic process.

5. Surgical intervention should be avoided in those cases of jaundice which show either of the above two sugar tolerance curves.

6. Intensive intravenous glucose therapy, by means of the continuous drip method, with cannula sutured into vein and arm immobilized in a cast, gives the most marked and most immediate beneficial results in these cases.

7. Visualization of the gall bladder with the oral administration of the dye was successful in seven out of eight of these cases in which it was attempted. The highest icterus index at which such visualization occurred was 66.

The Mechanism of Milk Clotting*

I. Role of Milk Components in Coagulation

By

I. NEWTON KUGELMASS, M.D.
NEW YORK, NEW YORK

MILK is a heterogeneous system of relatively simple composition. Its state determines the mode of utilization by the body and its content the nutrient value; the one is physical and variant, and the other, chemical and relatively constant. In pediatrics we are more concerned with the behavior of milk than with its content. And knowledge of the mechanism of clotting is invaluable in modifying milk for digestive tolerance.

The apparent simplicity of milk clotting is needlessly confused by terminology and theory. We have approached the problem by studying synthetic solutions containing the clotting compounds that are necessary and sufficient. By varying one factor, be it chemical or physical, the changes during clotting have thrown light on the mechanism. These physicochemical studies parallel those previously made of blood clotting (1). Indeed the clotting of milk with rennin is similar to that of blood with thrombin in the presence of calcium ions.

Three constituents of milk form the clot — caseinate, phosphate, calcium. They compose but two per cent of milk and yet play so determining a role. Their chemical relation in fluid milk is given in Figure 1 where concentrations are expressed in terms of normalities to indicate equivalent combining powers of basic and acid-forming elements to form the salts of milk. In cow's milk all of the calcium is combined with casein as calcium caseinate and with most of the phosphoric acid as calcium phosphates. The three clotting constituents of milk form the largest molecular aggregates.

Milk may be coagulated by rennin, acid, heat or by a combination of them. The resulting clot differs with each method although casein in some form is the end product. Rennet coagulation is most involved. Hammersten (2) first demonstrated that rennin hydrolyzes some of the casein to paracasein. Schmidt-Nielson (3) recovered this fraction with proteose-like properties as distinct from the original casein. Linderstrom-Lang (4) showed that rennet splits casein, a complex of several substances, into its constituents, the flocculating fraction being paracasein. Upon addition of soluble calcium salts Hammersten (5) obtained a flaky precipitate with paracasein and a tough clot when calcium phosphate precipitated with the paracasein. The rennet clotting of milk is thus a two-stage process, first considered physical by Lindet and Ammann (6), colloidal by Kreidl and Neumann (7), adsorption by Mellanby (8), chemical by Bosworth (9) and physicochemical by Palmer and Richardson (10). We have studied the changes occurring during coagulation by applying the technique developed for following the course of blood clotting.

PREPARATION OF COMPONENTS OF CLOTTING SYSTEM

Casein was prepared as a base-free protein by the method of L. L. Van Slyke (11) which yielded a snow white powder readily dispersed in alkali.

Calcium caseinate solution was prepared by dissolving 15 gms. of pure cesein in sufficient lime water to give a pH 8.0. The solution was neutralized to pH 6.5 with 1% H_3PO_4, 2.5 c.c. 0.1 M $CaCl_2$ added and then diluted to 300 c.c. It gave a 5% artificial milk of pH 6.5 preserved with 0.1 c.c. octyl alcohol and 0.1 c.c. toluol.

fresh from calves' stomachs preserved with NaCl, boric acid and thymol, dialyzed free from Cl and filtered. One c.c. of a 1% solution gave clot in 15 minutes added to 100 c.c. cow's milk at 40° C.

Buffer Solution was prepared by adding N/15 phosphate solutions according to Sorensen. A mixture of 4 volumes of the primary phosphate and 1 volume of secondary phosphate gave pH 6.3 confirmed potentiometrically.

Clotting Time: A definite amount of milk was placed in a test tube, rennet added, the tube inverted twice, placed in a water bath at 38° C. and the time recorded. The tube was then tilted from time to time and when the milk failed to flow as a fluid the duration was taken as the clotting time.

(A) Effect of Concentration of Milk Components on the Rate of Coagulation.

The clotting time of milk varies with concentration of each of the substances involved in the process. None react at the same time, nor at the same rate. A latent stage precedes the clotting stage and each milk component involved reacts accordingly in this heterogeneous system. Expressed mathematically, the rate of clotting is a function of caseinate,

$$-\frac{dc}{dt} = f\,[\text{Caseinate}]\,[\text{Rennin}]\,[Ca{+}{+}]\,[H{+}]$$

rennin, calcium ion concentration and pH. The rôle of each of these variants in relation to milk clotting time was determined by maintaining all others constant.

(1) Variations in the *volume* of the medium may affect the velocity of reaction. The clotting constituents were prepared in gradually increasing amounts but with the same concentrations in each system. The

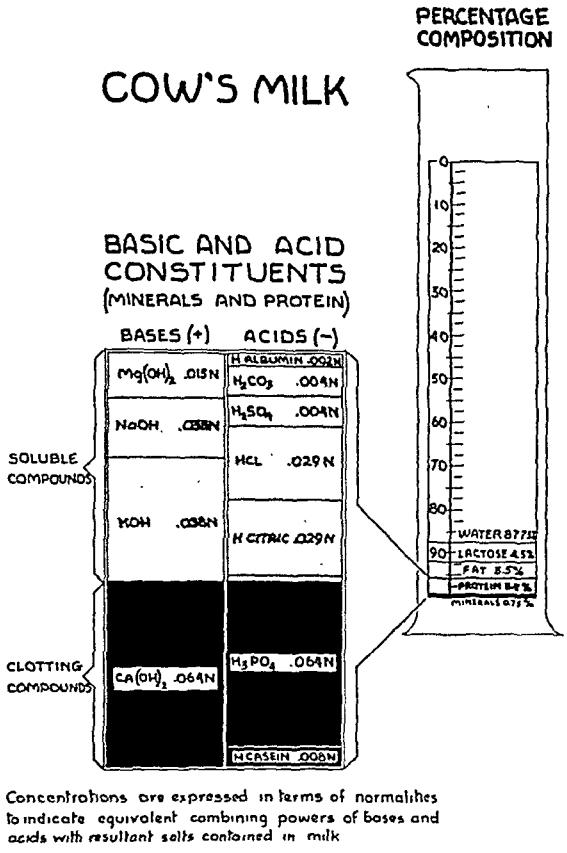

Fig. 1

clotting time was practically the same for each preparation. Apparently each of the clotting constituents react quantitatively upon one another according to chemical equilibrial relationships. (Table I).

(2) *Dilution* impedes velocity of clotting. The effect on milk was determined by adding increasing amounts of water to one series of clotting systems and finally adding large amounts of water to effect extreme dilution. While the clotting time diminishes rapidly, the rate is less than the degree of dilution. In fact beyond 1:100 the clotting time is practically constant. (Figure 2). The tough curd formed in the concentrated clotting system gives way to a gelatinous curd in the dilute system, then to a flocculent and finally to a gritty, in extreme dilutions. This effect on the character of the curd is due particularly to dilution of calcium ions.

Table III gives also the logarithmic values for each dilution and the clotting times respectively. The logarithmic curve (Figure 3) indicates an autocatalysis wherein rennin is reformed after reaction in the more concentrated clotting systems. And the tangent of the curve before becoming asymptotic is a measure of renning reformation. The horizontal curve indicates the prolonged but constant clotting time for spontaneous souring at every dilution. The curd tension varies inversely with the clotting time and the character of the curd is indicated. Similar relationships are graphed for the clotting of milk diluted with water in various proportions.

(3) Rennet concentration markedly affects the rate of milk clotting. Rennin splits caseinogen into paracasein, H+ increasing the velocity of Cleavage but Ca++ being unnecessary for this first stage in the clotting process. Table IV gives the data for the clotting systems graphed in Figure 4. With relatively large amounts of rennet, the clotting time is practically proportional to the rennet content. But with relatively small amounts of rennet the clotting times are prolonged rather indefinitely. There is an inverse proportionality between the amounts of rennet added and the resulting clotting time. In other words the clotting time is a logarithmic function of the rennet concentration. The character of the curd likewise varies with the rennet concentration—tough with rapid clotting times and flocculent with slow rates of clotting and small concentrations of rennet. The general equation maintains

(Rennet Concentration) . (Clotting Time) = Constant.

(4) Caseinate concentration is a determining factor in milk clotting. Experiments were set up maintaining all clotting constituents in each solution but varying the calcium caseinate content (Table V). The concentration-time curve (Fig. 5) parallels that of rennin. A definite chemical relationship exists therefore between caseinate and rennin for the course of clotting is quantitatively dependent upon their respective concentrations. The general equation maintains,

(Caseinate Concentration) . (Clotting Time) = Constant.

(5) Calcium Ion concentration modifies the course of milk clotting. Addition of calcium chloride decreases the pH of the synthetic mixtures as well as of

milk. A millimol of $CaCl_2$ per liter reduces the pH by one unit. Calcium ions are necessary only for the second stage of clotting for rennin splits caseinogen into paracasein without the presence of calcium ions. If calcium is precipitated by adding sodium oxalate to

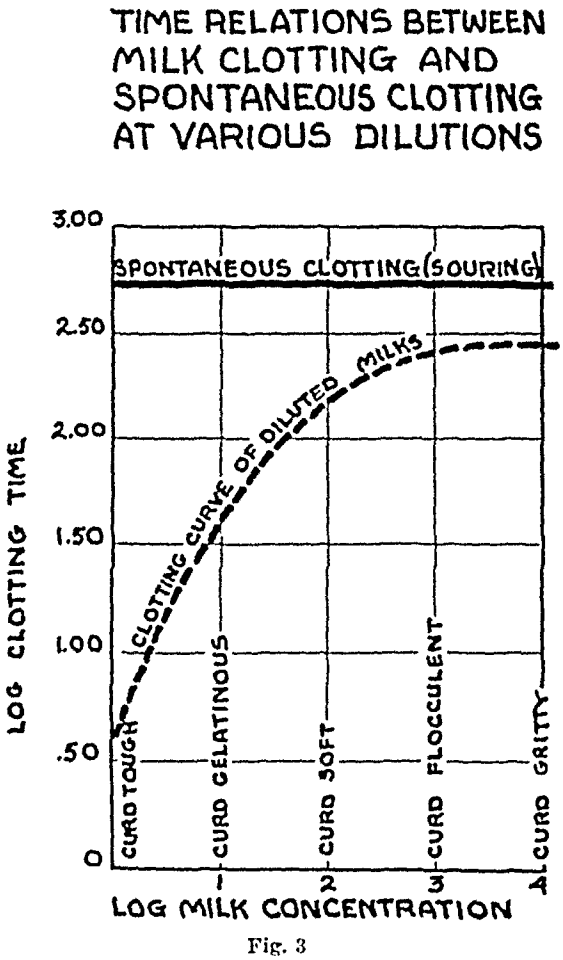

Fig. 3

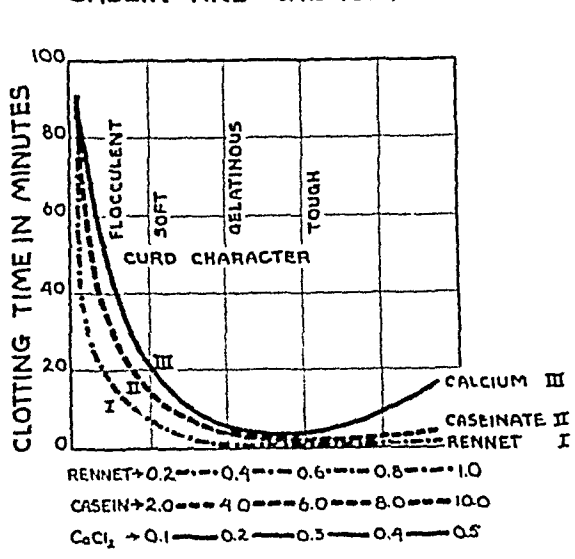

Fig. 4

milk or a synthetic milk mixture clotting does not occur on addition of rennin. If this solution is allowed to stand for an hour, then boiled to destroy rennin and $CaCl_2$ added clotting occurs. Rennin therefore acted upon carein without the presence of calcium. Any electropositive ion can replace calcium ions. Solutions with increasing amounts of molal calcium chloride were prepared for clotting time determinations (Table VI). Addition of Ca++ affects the state of aggregation and appearance of milk. It increases in whiteness prior to precipitation. The smaller the calcium ion concentration the greater the clotting time. This inverse proportionality maintains until 0.3 N calcium chloride when further increases in calcium ions actually prolong the clotting time (Fig. 5). Generally, however, the condition,

(Calcium Ion Concentration) . (Clotting Time) = Constant.

SUMMARY

1. Milk clotting involves the transformation of soluble caseinogen into some form of insoluble casein. With the action of rennin calcium paracaseinate is formed; with acid or heat, casein; and with more than one of these coagulants, a combination of these precipitates. Three constituents form the clot, caseinate, phosphate and calcium, consisting of but 2% of the composition of milk in the form of the largest molecular aggregates. The mechanism of milk clotting with rennin is similar to that of blood with thrombin, in the presence of calcium ions.

2. *The rennet clotting of milk is a diphasic autocatalytic process.* The first enzymic or digestive phase of clotting requires about half the time to develop the

curd, caseinogen being hydrolyzed into paracasein. Calcium ions are unnecessary for this stage in the clotting process. The second flocculation or active phase marks the appearance of calcium paracaseinate as a gel or precipitate. Calcium ions are necessary only for this second phase of clotting and both phases are accelerated by hydrogen ions. Calcium ions increase the whiteness of milk prior to flocculation.

3. The rate of clotting is a direct function of the concentration of the caseinate, rennin, calcium and hydrogen ions. The latter two prolonging clotting at higher concentrations. Diminution of any of these factors changes the character of the curd from tough to gelatinous, to flocculent and finally to gritty consistency at extreme dilutions, the curd tension varying inversely with the clotting time.

Influence of Fat on the Absorption of Dextrose from the Human Alimentary Canal*

By

MAX WISHNOFSKY, M.D., ARTHUR P. KANE, M.D.

and

WILLIAM C. SPITZ, M.D.

BROOKLYN, NEW YORK

DURING the past decade there has been a renewal of interest in the factors governing the absorption of dextrose from the alimentary canal. To a considerable extent this interest was initiated by Cori (1), who, in 1925, as a result of an ingenious method by which absorption of saccharides from the entire gastro-intestinal tract of rats was studied, came to the conclusion that (1) a proportionality exists between the absorbing surface of intestine and the body weight in growing male and female rats, and (2) the rate of absorption of hexoses is constant and is independent of the absolute amount and of the concentration of sugar present in the intestine. Trimble, Carey and Maddock (2) utilizing Cori's technic in dog's, made substantially the same observations. Magee (3) is also in agreement with Cori.

MacKay and Bergman (4), Pierce, Osgood, and Polansky (5), and Burget, Moore, and Lloyd (6), also employing Cori's method of study, made findings entirely at variance with those of the latter.

Ravdin and his associates (7), found that the rate of absorption of dextrose from a loop of intestine is increased with increase in concentration or volume of solution used.

Solutions of dextrose of varying concentration placed in the stomach are rapidly changed, so that when the solution reaches the small intestine the variations in concentration are of a small order. They suggest that this fact may explain the difference in the rate of absorption when the gastro-intestinal tract is used as a unit and when only a single segment of this unit is utilized.

As a rule absorption of a single foodstuff does not occur physiologically. It is important, therefore, to study the rate of absorption from mixtures of substance. Cori (8) has done this with combinations of 2 sugars, 2 amino acids, of sugars and amino acids, of dextrose and lactic acid, and of dextrose plus alcohol. It was found with great regularity, that when two substances were fed simultaneously, the rate of absorption of each was reduced. Thus, when dextrose and galactose are absorbed from a mixture of equal parts of these 2 sugars, the rate of absorption of both sugars is reduced to such an extent that the total amount of sugar absorbed is not greater than if dextrose alone or galactose alone were being absorbed. This is termed "mutual inhibition of absorption." This phenomenon was also present when a mixture of dextrose and glycine was given. Cori also states that absorption of dextrose from a pure solution proceeds much more rapidly than from a mixture of foodstuffs.

Experiments by Cajori and Karr (9) confirm the findings of Cori as to the rate of absorption of mixtures of dextrose and galactose from the intestines. Mahler and Nonnenbruch (10) found that (1) animal charcoal given with dextrose delayed absorption (2) mucin delayed absorption only when thoroughly mixed with dextrose (3) yeast stimulated the villi and increased the rate of absorption of dextrose.

The experiments described have all been performed on animals and are direct in character. It has been assumed that the results obtained are applicable to man.

AUTHOR'S STUDIES

From the foregoing review of the literature, it can be seen that but little work has been done on the question of absorption of dextrose from a mixture of foodstuffs. The results of an investigation by an indirect method of the influence of fat on the absorption of dextrose from the alimentary canal will be reported in this paper.

If a certain adequate amount of dextrose is given to an individual suffering from diabetes mellitus, a blood sugar

*From the Diabetic Clinic and the Departments of Basal Metabolism and Medicine of the Jewish Hospital, Brooklyn, New York.
Submitted November 30, 1936.

curve of a certain height and length is obtained, which is of course higher than normal.

If the absorption of a certain amount of dextrose per unit of time produces a curve of a certain height, the absorption of a smaller amount per same unit of time in the same individual will give rise to a curve of lesser height, for the mechanisms which are concerned with the regulation of the concentration of dextrose in the blood will have less dextrose to metabolize. This also holds true for the glycosuria, which in any particular individual is directly dependent on the height of the concentration of dextrose in the blood: the greater the height, the greater the glycosuria; the less the height, the less the glycosuria. It has been shown by Wishnofsky and Kane (11) that if equivalent amounts of dextrose and starch are given to diabetics two days apart the curves for glycemia and glycosuria are identical. It is reasonable to assume that the same will hold true if equal quantities of dextrose are given two days apart. If on one of these days certain factors are introduced which will reduce the amount of dextrose absorbed, the curves for glycemia and glycosuria will be lower than on the day of control. It is this principle which is utilized in studying the influence of fat on the absorption of dextrose from the human gastro-intestinal tract.

METHOD OF PROCEDURE

Experiments were performed on eleven diabetics. To each of them 60 grams of dextrose, in a 20% aqueous solution, were given in the morning after a fast of 14 hours. Blood (venous) specimens were taken at the "fasting level" immediately before ingestion, 1½ hours and 3 hours after the ingestion of the dextrose. The sugar content of the blood was determined by the Folin-Wu method. The urine was collected at the end of 1½, 3, and 6 hours after the ingestion of dextrose, and its sugar content determined by Benedict's method.

Two days later, also in the morning after a fast of 14 hours, 60 grams of dextrose in a 20% aqueous solution were given and this was immediately followed by 120 grams of olive oil.* The blood was taken and the urine collected at the same periods as when dextrose alone was given. In the interval between tests the patients were on their customary diets. Those who had been taking insulin continued to do so.

ANALYSIS OF RESULTS

In Table I are recorded the concentrations of blood sugar and amounts of dextrose in the urine after the ingestion of dextrose and of dextrose and fat. Statistical analysis† reveals (1) that there is no significant difference in the concentrations of the blood sugar at the "fasting level," (2) that the concentrations of the blood sugar is significantly greater 1½ hours after the ingestion of dextrose, than after the ingestion of dextrose and fat. This also holds true for the glycosuria 0-90 minutes post cibum, (3) that there is no significant difference in the concentrations of dextrose in the blood three hours post cibum; nor in the glycosuria 1½ to three hours, and from four to six hours, inclusive, post cibum. How are these results to be interpreted?

TABLE I

Concentration of dextrose in the blood and quantity of dextrose in the urine of diabetics after the ingestion of 60 grams of dextrose and of 60 grams of dextrose plus 120 grams of olive oil

Case Number	Blood Sugar (mg. per 100 c.c. blood)						Urine Sugar (gm.)

It is at first necessary to take cognizance of the following: (1) It has been demonstrated quite conclusively that no appreciable amounts of dextrose are absorbed from the stomach. Absorption takes place almost entirely from the intestines. (2) It was observed by Ewald and Boas in 1886, and repeatedly confirmed, that fat decidedly inhibits gastric motility and secretion. It is not within the scope of this paper to enter into a discussion of the mechanism involved. The conclusions of Lim (12), who has done extensive work on this subject, may, however, be mentioned. He states: "Fat inhibits both the nervous and chemical phases of gastric secretion and motility. . . . Neither a nervous reflex, nor a reflex secretion from another organ is an essential mechanism of fat inhibition. . . .

*Olive Oil is 100% fat.

†The method of analysis used was that developed by R. A. Fisher (Statistical Methods for Research Workers, 3d, ed., London, Oliver and Boyd, p. 104, 1930).

This inhibition is probably brought about by a humoral mechanism." (3) We have found that fat, given alone in large quantities, to a large series of diabetics, does not in the slightest influence the concentration of dextrose in the blood. As this material forms the subject of another paper, it will not be elaborated on here.

It was stated above that the concentration of dextrose in the blood is significantly greater 1½ hours after the ingestion of dextrose, than after the ingestion of dextrose, and fat. (see Table I). This also holds true for the glycosuria 0-90 minutes post cibum. This effect may be produced by (1) slowing of the emptying of the stomach, or (2) reduction of the rate of absorption of dextrose from the intestines as a result of the presence of fat, or (3) both. That this effect is engendered entirely by the first factor, namely a retardation of the emptying of the stomach, is evidenced by the following: The concentrations of dextrose in the blood three hours after the ingestion of dextrose and of dextrose and fat are identical. The amounts of dextrose in the urine from 1½ hours to three hours, and from four to six hours, inclusive,—a period of 4½ hours, after the ingestion of dextrose and of dextrose and fat are not significantly different. (see Table I). This is an indication that the amount of dextrose absorbed when dextrose is admixed with large quantities of fat is the same as when dextrose alone is present in the intestine. During the aforementioned period, namely from 1½ to six hours, inclusive, after the ingestion of dextrose and fat, a sufficient amount of dextrose enters the intestine to admit of a rate of absorption equal to that of dextrose given alone.

DISCUSSION

In recapitulation, it may be stated that the study of absorption of mixtures of substances has not been extensive. Cori has performed a series of experiments using combinations of two sugars, of two amino acids, of sugars and amino acids, and of dextrose and alcohol. He has observed consistently that when two substances were fed simultaneously, the rate of absorption of each was reduced. This has been termed mutual inhibition of absorption. Thus, when dextrose and galactose were fed in a mixture, the total amount of sugar absorbed was not larger than if each sugar was fed separately. This was equally true when a mixture of dextrose and glycine was fed. Cori states categorically that absorption of dextrose from a pure solution proceeds much more rapidly than from a mixture of foodstuffs. Our results of a study of absorption of a mixture of dextrose and fat are in disagreement with this conception. We employed the gastro-intestinal tract as a physiological unit. Initially there is a reduction in the rate of absorption of dextrose which may be interpreted as a result of the retardation of the emptying of the stomach by fat. Soon, however, the rate of absorption of dextrose admixed with fat equals that of dextrose given alone.

SUMMARY AND CONCLUSIONS

1. A review of the literature on the absorption of dextrose from the gastro-intestinal canal is given.

2. The consensus of opinion is that dextrose is absorbed much more rapidly from a pure solution than from a mixture of foodstuffs.

3. An indirect method is described for the study of the absorption of dextrose from the alimentary canal of man.

4. Results obtained by this method indicate that the rate of absorption from the intestine of dextrose admixed with fat is not appreciably less than that of dextrose given alone.

Enzymic Efficiency in Avitaminosis

VII. Peptic Digestion in Vitamin B Deficiency*

By

BARNETT SURE, Ph.D.

and

ROBERT TROY HARRELSON, M.S.†

FAYETTEVILLE, ARKANSAS

THE literature on the efficiency of peptic digestion either in experimental polyneuritis or vitamin B deficiency in man is scanty and unconvincing. In 1926, Farnum (1) found feeding a beri-beri producing diet to a dog gradually decreases the total volume as well as the free and total acidity of gastric secretion. In the same year Cowgill and co-workers (2) reported that in mild cases of vitamin B deficiency in the dog, associated with anorexia, there is no marked change in the character of the hunger contractions. In the severe cases of this deficiency, in which anorexia is accompanied by nervous and muscular symptoms, there is gastric atony. Successful vitamin therapy is followed by a rapid improvement in tone of the stomach musculature. The only direct statement we are able to find in the literature concerning the influence of experimental polyneuritis or peptic activity is that of Farmer and Redenbaugh (3) who found marked reduction in peptic efficiency in polyneuritis columbarum in five pigeons. At that time (1925) the necessity for controlling the plane of nutrition was not fully appreciated. Recently Alvarez and co-workers (4) maintained two persons for six weeks and one for four weeks on a diet markedly deficient in vitamin B_1. The concentrations of hydrochloric acid and pepsin in the gastric juice were measured almost every day. In two subjects there were no definite changes in the gastric juice, and in the third the only changes consisted in two falls in acidity, each associated with a respiratory infection. These workers concluded: "The work here reported indicates that a diet deficient in vitamin B_1, by itself, is not likely to produce much reduction in gastric acidity. It is possible, however, that such a diet might reinforce the lowering effect on gastric acidity of fever induced by injections of foreign protein."

P = Pathologic; R = Restricted to the same plane of nutrition.

EXPERIMENTAL

Peptic digestion was studied in two series of experiments. A deficiency of the vitamin B complex was produced in 15 sets of animals and uncomplicated vitamin B_1 deficiency accompanied by varying degrees of polyneuritis in 24 sets of rats, according to the paired feeding technique previously described (5). The essential point of this feeding procedure is that the control animal of the same litter and sex was restricted to the same plane of nutrition daily as the avitaminotic rat. The composition of the rations is outlined in Table III. The control animals of the vitamin B complex set received Ration 1751 in which 10 per cent of the dextrin was replaced by an equivalent amount of Northwestern dehydrated yeast. The control animals of the vitamin B_1 set received the same ration as the polyneuritic rats but in addition 10 γ of Merck's crystalline vitamin B_1 daily.

The peptic digestion was studied according to the vicosimetric technique of Northrop (6). Twenty-five per cent glyceryl extracts were made of the stomachs in concentration of 1 to 20, ground with sand, shaken for 5 minutes, and allowed to stand at room temperature for 24 to 26 hours. The supernatant liquid was then decanted off and an equal volume of 25% glycerol added, shaken for 5 minutes, and recentrifuged. Kahlbaumm's casein was used, prepared according to Hammersten. The digestion was carried out in a thermostat at 37° C., employing the Oswald type of vicosimeters. The digestion was run at 10, 20, 30, 40, 50, 60, 70, 80, and 90 minute intervals. A

total of 674 titrations were made in this investigation. To save space, we are reporting, however, only 30, 60, and 90 minute digestions. The results are expressed in pepsin units described by Northrop (6). All of the data are summarized in Tables I and II.

mate controls. In the rest of the experiments the difference in rate of digestion between the avitaminotic rats and their controls are too small to be of any significance. Summarizing all the results, the pathologic animals showed an increase in peptic diges-

Peptic Digestion in a Deficiency of the Vitamin B Complex. In only two groups, 3491 and 3304, marked differences in rates of digestion have been observed. In each of these cases the pathologic animals have shown a more rapid rate of digestion than the litter

tion in the 30, 60 and 90 minutes to the extent of 14.3, 11.9, and 10.9 per cent respectively. There was no influence on the rate of the loss of body weight on rate of peptic digestion.

Peptic Digestion in Vitamin B_1 Deficiency Asso-

TABLE III
Composition of rations

	Number of Rations			
	1751	2345	3148-A	3148-X
Casein (Commercial)	—	—	16	16
Casein[1]	20	10	—	—
Salts No. 185	4	4	4	4
Agar-agar	2	—	—	—
Butterfat (filtered)	10	10	—	—
Dextrin	64	61	—	—

1. Washed for 10 days with acidulated water and extracted thoroughly with 25 per cent alcohol.
2. Autoclaved for 6 hours at 20 pounds pressure at the natural pH of the beef (round steak).
3. Dehydrated Fleishman's yeast autoclaved for 5 hours at 15 pounds pressure at the natural pH of the yeast.

ciated with Polyneuritis. There was considerable variation in rate of digestion of the 23 groups studied. Fourteen pathologic animals showed varying degrees of increase in the rate of peptic digestion compared with their litter mate controls restricted to the same plane of nutrition, while nine avitaminotic rats showed varying degrees of decrease in peptic activity compared with their controls.

Summarizing all the results for the 30, 60, and 90 minute periods of digestion, the pathologic rats showed an increase over their controls of 6.9, 3.5, and 3.7 per cent respectively. Varying degrees of paralysis and increase in per cent of the loss of weight had no noteworthy influence on the rate of peptic digestion.

CONCLUSION AND SUMMARY

The data presented in this paper conclusively demonstrates that neither in a deficiency of the vitamin B complex nor in vitamin B_1 deficiency associated with varying degrees of paralysis is there any significant change in the rate of peptic digestion when comparisons are made with litter mate controls of the same sex and restricted to the same plane of nutrition.

Unusual Course of Pelvic Abscess and Fistulous Tract*

By

HUGH BEATON, M.D.
FORT WORTH, TEXAS

THIS case is reported because of the long continued ailment and the very great distance between the source of infection and the external pointing of the abscess.

CASE HISTORY

The patient, male, nineteen years, was referred to me by Dr. Charles Clayton, orthopedic surgeon, with the following history:

In March, 1932, he developed an abscess on the outer middle third of the left leg, accompanied with the usual symptoms: pain, redness, swelling and elevation of temperature. He went to the City-County Hospital where the abscess was opened and drained. He was discharged in two weeks. *Two months later,* the patient had a recurrence accompanied by a discharge near the old scar. He returned to the hospital. A diagnosis of osteomyelitis of the descending ramus of the left ischium was made. He was operated on and a cast applied. He remained this time in the hospital for ten weeks, being discharged the last week of *August, 1932.*

Three weeks after leaving the hospital, the patient noticed that he had some drainage from the original opening. That condition continued until July, 1933. He was again hospitalized and drainage instituted, by wide exposure of the femur on its lateral aspect. He was discharged at the end of ten weeks. When he left,

Fig. 1. Roentgen film after injection of fistulous tract with opaque substance. The size, course and internal termination of the tract are well demonstrated.

*Read at the Annual Meeting of the American Proctologic Society, Kansas City, Mo., May 11, 1936.
Submitted May 19, 1936.

the wound had apparently healed; however, in about three weeks he noticed some drainage, and had more or less drainage until June, 1935, when he was again sent to the hospital and operated on. After another ten weeks in the hospital he was discharged September 5, still with some drainage.

The latter part of October, 1935, the patient was

Fig. 2. Foreign body removed from pelvic termination of fistulous tract (slightly enlarged).

sent for X-ray study to Dr. X. R. Hyde, who was able to demonstrate that the sinus extended inward to the rectum. Shortly afterwards, I saw him in consultation with Doctors Clayton and Hyde. At that time, after careful study of X-ray plates along with proctoscopic examinations, I became convinced that the source of infection was in the anal canal.

The patient was sent to the hospital and on January 20, 1936, under avertin anesthesia, an antero-posterior incision was made in the left ischiorectal fossa, exposing the levator ani. The main tract was easily recognized by the great amount of granulation tissue lining it. A careful search was then made along the floor and sides of the exposed tract for off-shoots. I was now able to follow the main tract up between the sphincters and just as I got to the internal opening, I found what we believed to be the source of infection, namely, a foreign body about ⅞ inch long and ⅛ inch wide with ragged edges.

The main tract, including the external sphincter, was incised. All overlapping edges of skin and mucous membrane of the tract and fossa were removed. The wound was lightly packed with vaseline gauze.

POST-OPERATIVE TREATMENT

The sinus down the thigh was irrigated daily with hydrogen peroxide for about one week. The wound was irrigated every four hours with warm normal saline solution.

Drainage from the external sinus ceased about the sixth day. The ischio-rectal wound filled in rapidly. Temperature returned to normal and remained so, after four years of considerable elevation at times. The patient gained weight rapidly and has been working since March 1.

The interesting thing about this case would appear to be, did this patient have the anal infection before the osteomyelitis? I am inclined to think that he had, and that such infection was the reason for failure of previous operations although they were performed by skilled men.

Pepsin Versus Hydrochloric Acid in the Experimental Production of Gastric Ulcer*

By

MILTON J. MATZNER, M.D.†

and

CHARLES WINDWER, M.D.‡

BROOKLYN, NEW YORK

THE etiological factors in the production of gastric and duodenal ulcer in man have not been established (1, 2, 3). Peptic ulcers simulating those occuring in man, were first experimentally produced in dogs by Exalto (4) and Mann and Williamson (5). These investigations have been thoroughly reviewed by Graves (6). The effects of acid gastric chyme have been particularly stressed by most authors.

Buchner, Siebert and Malloy (7) have reported that subcutaneous injections of histamine produced ulcers in the prostomach of the rat. These authors as well as Burkle de la Camp (8) contended that the resultant increase in hydrochloric acid and possibly pepsin was responsible for these ulcers.

Both clinically and in animal experimentation the acid portion of the gastric chyme has been regarded as of greater importance than its pepsin content (9). Recent clinical observations of Vanzant, Osterberg, Alvarez and Rivers (10) and confirmed by Mullins and Flood (11), seem to indicate that peptic ulcer in man is frequently accompanied by an increase of pepsin.

It occurred to us therefore that a more direct approach to this problem could be made by controlled feeding experiments on rats, employing solutions of pepsin with hydrochloric acid and hydrochloric acid alone (12).

EXPERIMENTAL

Rats of the original Wistar strain, averaging in age 4 months were fed the Steenbock-Bills diet (13). Fresh lettuce or sliced carrots were added on feeding days. Fluids were supplied by means of stoppered flasks, with glass tube outlets attached to the cages. The rats were then able to partake of these solutions *ad lib.* At first we used a 20% solution of pepsin in 0.3% HCl. We have subsequently found that a concentration of pepsin as low as 1% is equally as effective.

These rats were divided into *two main groups:* a fasting

This work was aided by a grant from Mr. E. L. Cowen.
Submitted May 19, 1936.

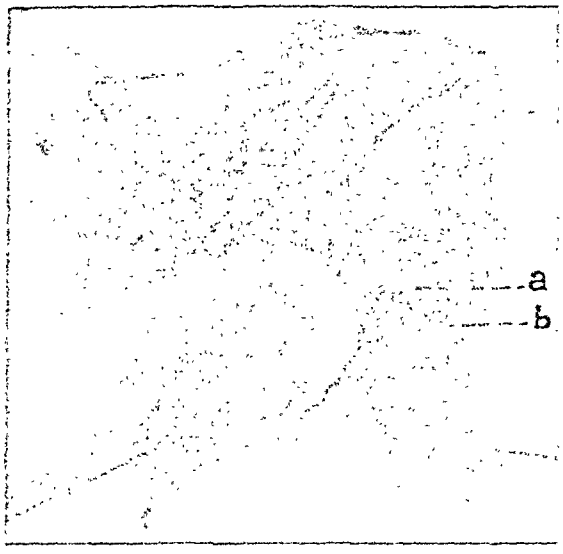

Fig. 1. Photograph of a portion of the pro-stomach of a rat showing a typical ulcer-like, gross lesion of the mucosa. Note the raised margins (a) and central depressed area (b) of the lesion.

and a non-fasting. In the *fasting group*, the rats were fasted for two days and were fed on the third, in recurrent cycles. The *non-fasting group* had continuous access to food. The experimental periods varied from 12 to 21 days, averaging in general about 16 days. The results in the fasting group are summarized in Table I.

RESULTS

In the fasting *Sub-group 1a*, which had continuous access to a 20% (by weight) solution of granular pepsin (1:10,000 Parke, Davis and Co.) in 0.3% hydrochloric acid we found that 96% developed one or more ulcer-like gastric lesions.

On the other hand, in a control *Sub-group 1b* that received only 0.3% HCl under similar conditions, only 16% developed these gastric lesions. In order to establish that the greater incidence in the pepsin hydrochloric acid *Group 1a* was actually due to the activity of the pepsin and not to any foreign substance it might contain, a group of animals received a mixture

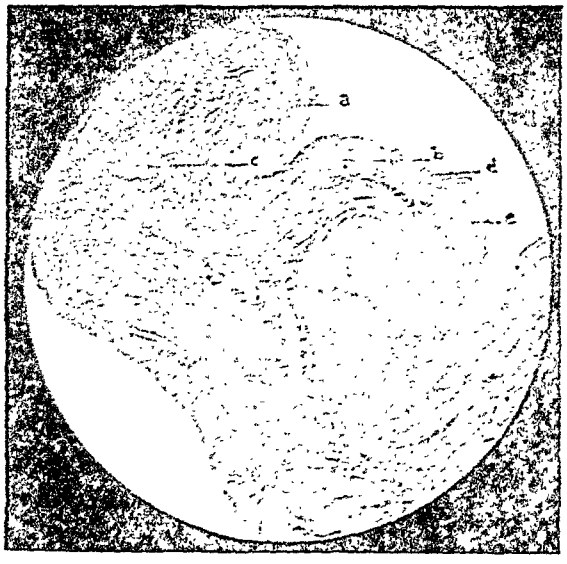

Fig. 2. Photomicrograph of a section of pro-stomach of submucosa (a) detaching the muscularis mucosae (b) from a *normal rat*. Note the intact submucosa (b) and its close proximity to the overlying mucosa (a) as well as to its underlying muscularis (c). The layers of stratified squamous epithelium are normal in every respect. The superficial cells (d) present only slight desquamation and the basal cell layer (e) is entirely intact.

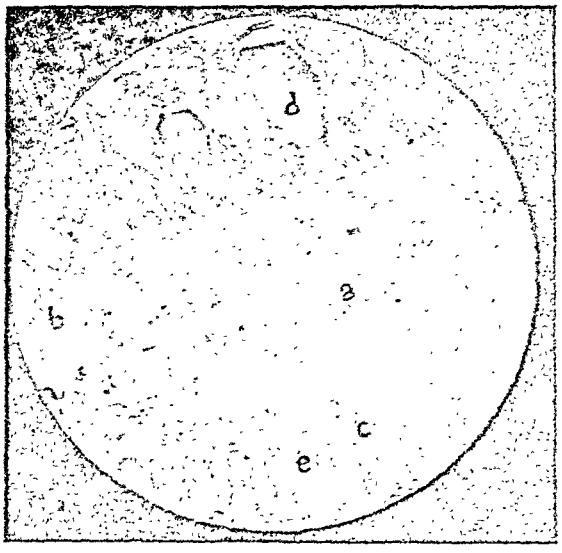

Fig. 3. Photomicrograph of a section of *a typical lesion* described in the gross. Note the marked edema of the submucosa (a) detaching the muscularis mucosa (b) from the underlying muscularis (c). Note also the extent of the infiltrate into the papillary bodies (d) and separation of the bundles of the circular layer of muscle (e).

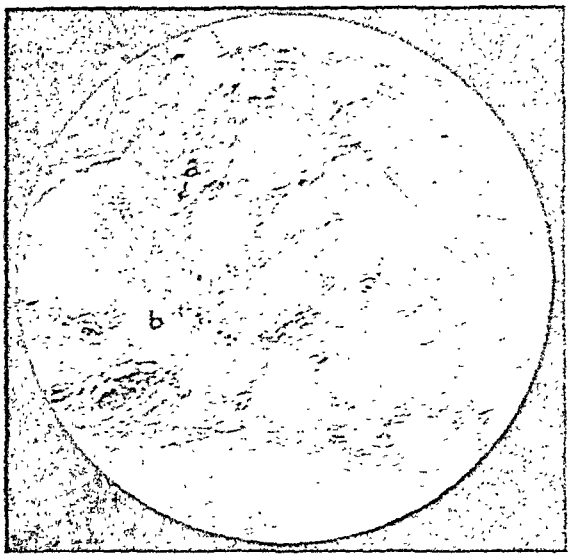

Fig. 4. Photomicrograph of another typical lesion showing marked desquamation of the lining epithelium. Note the point of complete denudation of the lining (a, with arrow) and the congestion and infiltration accompanying the edema in the submucosa (b).

Fig. 5. Photomicrograph of another typical lesion showing the disturbance of the basal layer of epithelium by the advancing infiltrate from the submucosa through the muscularis mucosae (a, with arrow). Note also the moderate degree of desquamation of lining epithelium (b) as well as congestion, edema and infiltration in the submucosa (c).

of inactivated pepsin (heat digestion) and hydrochloric acid. In the latter group we observed lesions in only 20% of the rats. This incidence almost corresponded to that of *Group 1b* that had received hydrochloric acid alone. This appears to establish that the far greater incidence in the pepsin hydrochloric acid group was definitely due to the activity of the pepsin.

That fasting was not the sole cause of these lesions appears to be established by the fact that in *Group 1d* 15 rats with similar fasting periods and continuous access to water alone, no gastric lesions were observed.

The results in the *non-fasting Group 2*, which had continuous access to food are summarized in Table II.

In the *Sub-group 2a*, which had continuous access to a solution of pepsin and hydrochloric acid, we found only 20% developed gastric lesions as compared to 96% incidence in a similar *group 1a* subjected to fasting periods.

Furthermore, no lesions were observed in the *Sub-group 2b* that had continuous access to HCl alone, as compared with an incidence of approximately 16% in rats under similar conditions in the fasting *Group 1b*. Although the absolute incidence of gastric lesions in the non-fasting 2a and 2b is not as great as in the fasting group, the relative incidence is similarly apparent.

To further establish that no foreign substance was present in the pepsin preparation, 20% dry pepsin (by weight) was incorporated in the diet. No gross lesions were observed in any of these rats, 2c. In 60 additional control rats, 2d, on various complete stock diets, no gross lesions were observed at autopsy.

DESCRIPTIONS OF LESIONS

Before describing the observed lesions, the normal anatomical findings in the rats' stomach may be briefly reviewed. The rumen or prostomach is sharply divided from the glanular portion by a smooth, elevated linear ridge, which passes to either side of the cardiac orifice. Histologically, (Fig. 2), the rumen, including the limiting ridge, is lined with squamous epithelium, covered by a thin keratin layer. The epithelium rests almost directly upon the well developed muscularis mucosae, from which it is separated by delicate connective tissue. The muscularis mucosae is separated from the muscularis by areolar connective tissue of the submucosa.

Gross Description: The observed lesions (Fig. 1) were frequently situated in proximity to the limiting ridge and along the lesser curvature. However, other portions of the rumen were often similarly involved. These lesions, which varied in number, were usually discrete, though at times they appeared confluent. Their margins were raised and the base of the umbilicated center appeared brown or red. They measured approximately 0.5 to 5 mm. in greater diameter.

d	60	Additional controls on various stock diets.			21	Negative.	0	0	0

Microscopic Description: The most constant finding consists of focal areas of submucosal edema, which detach the muscularis mucosae from its underlying coat and which in areas also involve adjacent mucosal as well as muscular layers. In the latter coat, the edema produces separation of the bundles of the inner circular layer of the muscle while in the former (mucosal layer) the edema of the papillary bodies produces wide separation of the epidermal pegs. In most of the areas a pronounced cellular infiltrate and increased vascularity accompany the edema. The exudate consists of extravasated red cells and varying numbers of polynuclear, round and plasma cells (*Fig. 3*).

The extension of the above described infiltrate of the submucosa into the basal layer of the epidermis, distorting the normal architecture of the latter, especially, in the latter region of the stratum germinativum, is of especial interest.

Other less extensively involved areas, present in addition to the edema, congestion and increased number of blood cells. The above changes are most marked at sites corresponding to the elevated margin of the lesions described in the gross.

A less constant finding consists of desquamation of the lining epithelium in the center of some of these lesions. In areas, the process is advanced to a degree deserving the term "erosion," since the mucosa at these sites is almost completely denuded. At times the desquamation is observed to the degree of complete denudation of the lining membrane.

DISCUSSION

These experiments would seem to prove that pepsin rather than hydrochloric acid is the important agent in the experimental production of gastric ulcer in the rat. While our work was in progress, Howes, Flood and Mullins (14) reported that operatively produced gastric defects in cats showed a greater delay in healing in those receiving pepsin with acid, as compared to those receiving acid alone.

The selective localization of these lesions in the rats' prostomach is of extreme interest. This region is lined by squamous epithelium (a site unusual for peptic ulcer in man). Ulcers only occur occasionally in the glandular portion both in our experiments and in those reported with histamine injections (7, 8). Why histamine (15, 16) and a pepsin containing acid extract of pigs' stomach (17) produced gastric lesions in cats and dogs (lined by glandular epithelium) and why with similar agents in the experimental rat, the prostomach (lined by squamous epithelium) was the seat of election for these lesions, remains unanswered at present.

The dependence of these lesions upon alternating fasting periods, as evidenced by a 96% incidence in the pepsin-HCl fasting group, compared to only 20% in the non-fasting group is likewise very significant. In the light of possible amino acid deficiency, originally suggested by Weiss and Aron (18) experiments are in progress with the simultaneous administration of histidine monohydrochloride and other essential amino acids. The results will be published.

This rapid and simple method of ulcer production in a readily obtainable laboratory animal should afford opportunity for the further study of the role of pepsin in the activation and tendency toward chronicity of peptic ulcer in man.

CONCLUSIONS

1. Pepsin in an acid medium is far more effective than is hydrochloric acid alone in the experimental production of ulcer-like gastric lesions in the albino rat.
2. Fasting appears to be a very important factor.
3. This rapid method of producing ulcers is suggested for the study of the prevention and the treatment of peptic ulcer.

IN WHAT WAY DOES A FULL STOMACH ADD TO THE TROUBLES OF A FAILING HEART?

IT must always be disturbing to a gastro-enterologist to hear that the elderly man whom he treated for a time for flatulent indigestion dropped dead a few months later with an attack of angina pectoris. The questions will then arise: Was not the man's feeling of gas pressure the earliest symptom produced by the diseased coronary artery, and should not this possibility have been suspected in time so that the man could have been protected from the dangers of overexertion? What was there peculiar in this particular history which should have warned the physician that he was dealing with a *failing heart and not with an* upset stomach or a diseased gall bladder?

In looking back over the histories of some of these patients one finds little that could have warned a physician as to the true state of affairs. Often there is no question about the fact that the distress was in the epigastrium and not in the chest; sometimes it was almost in the gall bladder region, and in some cases there were good reasons for diagnosing cholecystitis. In other cases heart trouble was thought of, because in some ways the story suggested it, but unfortunately there were so many elements that pointed to a neurosis that when the electrocardiogram was reported as almost normal, the thought of coronary disease was dismissed. Perhaps in most of the cases the story indicating heart disease either was not elicited or else was not given sufficient attention.

Now what are the symptoms that should have been looked for in a man past middle age complaining of pressure distress or pain in the epigastrium? The most diagnostic one would have been that this distress followed, not the taking of food, but exertion, and particularly exertion after eating. On being questioned more carefully, the man might have stated that after eating he could not walk a block without getting the distress so bad that he would have to stop and wait a few minutes until it passed off. Perhaps also, if the man came from the colder parts of this continent he might have remembered that the pain came sooner if he tried to walk *in freezing* weather.

Or if the man was accustomed to dig in his garden or to play golf strenuously over the week-end he might have noticed that he usually had a restless gassy or wheezy night after this extra exertion. Commonly such a patient will be found to have a high blood pressure. Many of these people with hypertension seek out the gastro-enterologist because they belch or feel distended with gas.

For many years, and probably since the time of Hippocrates, we physicians have been accustomed to recognize the type of patient who cannot exercise after a good-sized meal, but we have probably been wrong in assuming that this difficulty arises because the full stomach presses up on the heart. Although it is possible that the heart's action can be disturbed in so simple a mechanical way, it now seems more probable that the embarrassment of the organ arises in the fact, well demonstrated by Herrick et al (1) and McCracken et al (2) that after a meal, the blood flow more than doubles, not only in the blood vessels supplying the digestive tract, but also in all the vessels of the rest of the body. Now that this has been demonstrated, one can easily see why a man whose heart is ordinarily just strong enough to stand the extra strain of a short walk is not able to take this walk after meals when the load on the circulation has already been increased almost to the breaking point.

Walter C. Alvarez, Rochester, Minn.

COLONIC "VOMITING" DUE TO FAULTY EATING

"WHO hath put wisdom in the inward parts, or who hath given understanding to the heart?" (1). By means of this power for "reasoning," the heart automatically controls the circulation of the blood. But may there not be still unknown "wisdom" in other inward parts? Does not the stomach exhibit "wisdom" when, as the result of overindulgence, it rejects what has been put into it by the abnormal act

Submitted February 20, 1937.

of vomiting? It does; for, through such act, this "primary" digestive pouch serves to protect the body from the absorption of injurious substances in extremely unsuitable food. Moreover, in another act of the digestive system as a perfect nutritive apparatus, according to the hypothesis of Burnett, the large gut appears to serve as a "secondary" digestive pouch. The proximal colon, by analogy, should exhibit a power of "reasoning" similar to that of the stomach; for in it, when food consumed has been thoroughly comminuted, made complete and properly proportioned and is not mixed with laxatives, the aliment is retained. It is kneaded back and forth by waves of peristalsis and antiperistalsis, and thus completes its cycle of digestion and absorption (2). But when the ingested mixture is abnormal, the colon "vomits," as is manifested by diarrhea or soft stools. Thus, this "secondary digestive pouch" serves to protect the body from the absorption of injurious substances contained in unsuitable food.

The proof of this action is not only shown by abnormal forms of the feces but also by an abnormally fast passage of a marked evening meal through the bowels, *i.e.* a rapid intestinal rate (3). In these circumstances, while the dejections may be irregular, yet a portion of this meal, delimited with seeds or another marker, is frequently discharged in about thirteen hours, and at the latest, is seen in about sixty-three hours. Whereas, when the colon is not "vomiting," one, and sometimes two, entirely segmented or normal stools are common daily: yet such meal residues do not appear for about sixty-two hours, and, at the latest, are seen in about one hundred and thirty-four hours. *Such time is considered to be the normal intestinal rate.* The method of testing it appears to be the most exact way of knowing about the nutrient substances which are assimilated by cells in the final and most important phase of "anabolic" or normal nutrition.

The construction and maintenance of the cells from this point of view receive support from established physiological principles. In the *first* place, if completely segmented feces are normal for the higher animals, it is reasonable to suppose that they are normal for the highest animal, man. *Second,* the formation and action of the proximal colon which molds these segments is normal for the higher animals; for there the aliment is kneaded back and forth, and then a segment from its contents is, every now and then, nipped off by a ring of constriction, and carried away to be moulded, (in its further passage down the colon) to the firm fecal nodule (4). A rapid passage of the colonic contents in animals, due to unsuitable food, has been observed (5). This is abnormal and can be regarded as "vomiting" by the colon. The slow passage of uniform segments of the intestinal contents through the distal colon of man has been described by Fischl and Porges (6); and this is the normal. Whereas, the rapid and propulsive passage of large and irregular masses of the colonic contents from caecum to rectum of man has been observed by Holzknecht (7); this is abnormal: it is a sign of "vomiting" by that part of the bowel. According to this hypothesis, when the molding of formed stools in the secondary digestive pouch prevents such "vomiting" by the colon in patients whose diets are adjusted and erroneous ways of eating are avoided, it is reasonable to presume that such action of the proximal colon is normal for man. *Third,* when patients, and especially those in a "health class" for skin diseases at the Massachusetts General, and in one for arthritis at the Peter Bent Brigham, Hospitals, apply these measures, frequently they become relieved of the consequences of a faulty diet, and become healthy. Furthermore, since some diseases have for a long time been supposed to be of *metabolic* origin but such were without sound and scientific principles by which they could be treated, now through the understanding and application of the *anabolic* processes, the previously unrecognized cause of some of the "metabolic" diseases may be removed (8, 9).

From this point of view, "health" becomes not always a vague and variable condition of the human body, as ordinarily thought but, at times, may be an exact and improved state of well-being about which relatively little is yet known. To create optimum health, patients are advised to eat very slowly, to avoid the consumption of irregular, incomplete, and disproportioned meals and to abandon the use of laxatives. By such cautions, the patient is supposed to benefit from the food consumed. Only giving patients lists of food is valueless in support of these principles. Each patient must learn to operate his own nutritive apparatus normally by *how* and *what* he eats. In place of such hap-hazard directions, our patients are requested to keep a week's record of their nutrition, by writing down all the food consumed, the time spent at meals, the time and kind of their dejections, and to perform a test of the "intestinal rate." These records are kept and examined every few weeks in the beginning of treatment. When "vomiting" by the colon is evident, further "health" adjustments are advised in accordance with the requirements of *each* subject. After the records show stools of normal character and the time required for a meal to pass through the bowel is within normal averages, often one observes that the red, scaling, and disfigured skins of patients with eczema or psoriasis, or the swollen, stiff, and painful joints of arthritis which have existed for long periods, become relieved. In these circumstances, since a state of "health" has been created which relieves disease, it seems obvious that this state of nutritional health subsequently must be controlled in order to prevent recurrences. If these principles of dietary and physiologic treatment are continutd, such results can be accomplished (10). Former patients are required constantly to observe their dejections and to keep them normal and to obtain two sets of normal figures of their intestinal rates and of their weights each month. When these results are abnormal the patients are advised to return for discussion of their disturbances or are enrolled in the "health class" immediately. Even when they are well, these healthy persons are advised to return several times a year with required figures and a week's record of their food-intake so that the physician is convinced that they continue to be normally nourished and healthy. At one of these visits, a thorough and exact "health" examination is made; this gives subjects added assurance that, when they prevent their colons from "vomiting" by taking proper food and by careful living, they are able to control the exact and the improved state of health which has followed from *"anabolic nutrition"* and which has acted favorably upon their ailments.

Book Reviews

Les atrophies gastriques dans les anémies idiopathiques et les mé tanémies. By Robert Lehmann. Le Francois, Paris, 1936, pp. 118, 5 plates.

A COMPARISON of the different forms of anemia with the condition of the gastric mucosa is attempted. It is entirely based on gastroscopic observations. X-ray findings have been considered also, but the author does not attribute much of value to them. The cases of idiopathic anemia observed clinically and gastroscopically have been subdivided into four groups: (1) Anemia of Biermer, (2) Hypochromic achylic anemia (or severe chlorosis), (3) Aplastic anemia, (4) Intermediate malignant anemia (Chevallier), containing those malignant cases which do not correspond with any of the other groups. The atrophy of the gastric mucosa is subdivided as usually into patchy and diffuse atrophy. 19 observations are reported extensively, but this figure appears to be not entirely sufficient to justify all the conclusions. However, it is of great importance that the author confirms an observation made at first by Jones, Benedict and Hampton, namely that the atrophic areas respond to therapy and that regeneration of the atrophic mucosa is possible. He believes that usually the patchy atrophy is healed by liver treatment, and that diffuse atrophy responds to iron. The bibliography is excellent, and the small book will be of great value to the hematologists as well as the gastro-enterologists.

Rudolf Schindler, Chicago, Ill.

Physiology in Health and Disease. By Carl J. Wiggers, Professor of Physiology in the School of Medicine of Western Reserve University, Cleveland, Ohio. Second edition. Cloth, 1124 pages with 191 engravings. Price $9.00. Lea and Febiger, Philadelphia, 1937.

THE appearance of a second edition two years after the first printing indicates the favorable reception which this publication has received and is further evidence of the author's efforts to keep abreast of current developments in physiology and clinical medicine. As with the first edition, this edition is intended primarily as a textbook for medical students but it is written in accord with the author's conviction that clinical medicine should be approached from the physiological aspect since disease is essentially Nature's experiment in physiology. The book stresses the application of pure science to physiology, inculcates general principles of physiology, outlines and surveys the function of various tissues, organs and systems and emphasizes in masterly fashion the methods and procedures by which physiological knowledge is adduced. Having devoted a lifetime to an unusually fruitful investigation of the heart and circulation, the author has treated these subjects most exhaustively and with a degree of success probably not approached by any other publication. The other organs and systems of the body in both health and disease are also thoroughly considered. In partial evidence of this fact it may be noted that approximately 100 pages are devoted each to the gastro-intestinal tract, respiration, blood and blood formation, metabolism and nutrition, endocrine organs and reproduction and nearly 200 pages to the nervous system. In the second edition a number of physiological concepts have been recast or amended to make a readjustment of emphasis in accordance with the rapid progress of contemporaneous research, clinical material has been used to even a greater extent in discussion of physiological principles and clinical conditions have been analyzed as completely as possible by application of facts and concepts established by experimental means. Unusually abundant references to the American, English, French and German literature are given. Especially valuable is the listing of nearly all the outstanding review articles, monographs and texts recently published in this field. To the student of physiology or the clinician who seeks the ultimate exposition of body processes in health and disease, this book will be invaluable.

J. P. Quigley, Cleveland, Ohio.

Man the Unknown. By Alexis Carrel; Harper & Brothers, $3.50, 322 pages and index.

IN this book Carrel states that if an intelligent man continued to study exclusively until he was fifty years of age, he could probably acquire by that time a good working conception of all existing human knowledge. Carrel himself, having had ample opportunity, has probably come nearer to fulfilling this particular condition than any other man alive. With the advantage of this training he sets out in this book to summarize all of the extant knowledge about man. The book is the first scientific attempt of this kind in history, and though it may have the faults of first attempts, nevertheless it has many excellent points.

Carrel points out that of all the things that man knows, that which he needs the most and knows the least, is a thorough knowledge of man himself. He indicates that civilization carries with it the seeds of its own destruction. The records of the past confirm this; each civilization has slowly risen to a climax and

then rapidly crashed. Our civilization is the first one in known history which is conscious of its own impending destruction and has sufficient knowledge on hand to know how to prevent it, if it will only get busy. Will we do that? asks Carrel.

The only way to begin it, is to go at it in some such way as he is doing, by first collecting and correlating all knowledge concerning man himself.

In his summary of the knowledge of man he goes down to fundamentals and begins with physics and the philosophy of physics. He stimulated the reviewer to secure Bridgman's book and master the theory of the operational concept, and has found it valuable in daily medical practice all the way from working out a complex diagnosis to evaluating a drug advertisement. Chemistry, anatomy, physiology, are all rapidly and carefully summarized. From the amount of space devoted to psychology, or the mental aspect of man, one concludes that Carrel considers this phase of man the most important in the problems to which the book is devoted.

He incidentally touches on the fields that are not at present recognized as scientific. He discusses quite frankly the reported phenomena of mysticism, telepathy, clairvoyance, and miracle cures. This feature of his book has produced no small sensation among its readers, especially those in the medical circles. The publishers rode it as hard as they could as a publicity stunt. However, on careful examination it will be found that this feature occupies about the amount of space and has received about the amount of attention that it deserves. Carrel gives no impression of having been carried away by these things; he has observed them and is interested and is watching them in a scientific way.

Human ecology has received some original treatment. He demonstrates man as the most adaptive of all living organisms to external environment, but as unable to adapt to the environment which he himself builds up about himself. Man builds up civilization to which he cannot adapt. He is not adapting to the present civilization. Will he lose his civilization, or will he adapt by learning? Carrel seems to be intrigued by the question of what effect man's diet has upon his activity and his history. He wonders what peoples ate who achieved heroic and historic things in the past.

Repeatedly in the book he comments on the increasing complexity of our knowledge, and feels that this is only apparent and probably due to the deficiency of the means at our disposal for observation. He feels that Nature at the bottom is fundamentally simple, but to our limited perceptions, seems as complex as does the elephant to the blind man.

His arguments urging asceticism have been much commented upon. Properly interpreted, his attitude on asceticism is not fanatic; it is merely reasonable in the face of the modern tendency toward excessive comfort and diversion. History has confirmed the fact that comfort, lack of discipline, and a multiplicity of stimuli, destroy the initative and capacity for hard work that is necessary to the human being for success in adaptation to environment and the survival of the species.

The book is not easy to read. Although the sentences are short, they are dogmatic, and they are packed full of meaning so that many a short sentence may have to be repeatedly reread before its full significance is carried on into the paragraph. Although finishing the book does not exactly leave one in a state of back-slapping optimism, it is nevertheless highly stimulating to thought; and it is to be hoped that it is the first of a series by awakening minds which will bring back to discipline a civilization that is rapidly approaching its zenith.

Miles J. Breuer, Lincoln, Nebraska.

"La Sécrétine." By Jean La Barre. Bibliothèque Scientifique Belge. Published by Masson & Cie., Editeurs, Paris, 1936, 272 pp. Price, 30 francs.

FOR several years, with the assistance of his numerous co-workers, Jean La Barre, who is a Professor in the University of Brussels, has studied the physiological and chemical properties of secretin extracted from the duodenal mucosa. According to his view secretin, which is liberated by the hydrochloric acid of the chyme when it enters the duodenum, possesses two properties, (1) that of stimulating the secretion of pancreatic juice, and (2) that of lowering the blood sugar level. Both are properties of one and the same chemical body. However, by special chemical methods the particular part of this chemical body that stimulates pancreatic secretion—namely, "secretin"—may be separated from the part which produces hypoglycemia, and to which La Barre gives the name of "incretin." "Purified secretin," having either a very insignificant or no effect on the blood sugar, has been obtained by many investigators (Mellanby, Still, Ivy, Agren and others). La Barre succeeded in obtaining from the duodenal mucosa a product which was practically devoid of any secretagogue properties, but which retained its ability to reduce the blood sugar. Two different methods were used by La Barre in separating "incretin" from "secretin." As a source of "incretin" he employed a crude secretin extracted with a 0.5 per cent solution of HCl from hog's intestinal mucosa. One method was based on the solubility in ether of "incretin," precipitated from secretin by trichloracetic acid. However, a much better yield of "incretin" was obtained by the other method, namely, by the peptic hydrolysis of secretin obtained by precipitation with ammonium sulphate.

The physiological properties of "incretin" are as follows: It does not lower the blood pressure and is practically devoid of any secretagogue effect on the pancreas. Two to three hours after the intravenous administration of "incretin" in doses of from 5 to 10 mg. per Kg. body weight in a rabbit or dog, the blood sugar falls to a convulsive level. In contradistinction to insulin "incretin" may produce a hypoglycemic effect on being introduced through the mouth. For oral administration a dose of "incretin" three times larger, *i.e.* 15 to 30 mg. per Kg. body weight, is required in order to produce a marked fall of the blood sugar level. The maximum effect is reached in about four hours. The hypoglycemic action of "incretin" is of a double nature: (1) it stimulates the secretion of insulin, as was proved by the method of cross-circulation in two dogs, and (2) it has a direct hypoglycemic property, because it lowers the blood sugar level in depancreatized animals. La Barre succeeded in keeping depancreatized dogs in good health for several weeks by administering to them daily by mouth 30 mg. of "incretin" per Kg. body weight. "Incretin," like insulin, increases the deposition of glycogen in

the liver, and diminishes the glucose content of the venous blood of muscle. It increases the motility of the stomach and the secretion of gastric juice.

La Barre, in ten cases of human diabetes, studied the effect of "incretin" introduced by mouth in daily doses of from 0.5 to 1.0 gm. In mild cases of diabetes (hyperglycemia, 0.26 per cent; glycosuria, 0.57 per cent; traces of acetone in urine) such doses of "incretin" were sufficient to reduce the blood sugar to 0.14 per cent and abolish the glycosuria and acetonuria. In more severe cases of diabetes (hyperglycemia, 0.33 per cent; glycosuria, 1.4 to 1.3 per cent) after five days' treatment with 1 gm. of "incretin" the hyperglycemia showed a decrease, the blood sugar being reduced to about 0.13 per cent, and the glycosuria was diminished to 0.1 per cent. However, while "incretin" may be useful in mild cases of diabetes, La Barre believes that in severe cases of the disease it is advisable to combine "incretin" with insulin, because "incretin" performs two functions—it stimulates the endocrine function of the pancreas and it acts directly on the tissues, enabling them to assimilate carbohydrates.

Besides a thorough exposition of the facts relating to the hypoglycemic effect of secretin, the book contains a wealth of other information concerning secretin, as well as the different methods of preparing it and its physiological action on different organs. The book is written in a lucid style and the facts are clearly set forth, so that it makes very pleasant reading. Every quotation is accompanied by a reference to its source in the literature. There is an index both of authors and subjects.

It seems to the present reviewer that the appearance of Professor La Barre's book is most timely. It establishes an important relationship between the gastro-intestinal tract and one of the fundamental functions of the body, namely, the utilization of carbohydrate—a type of bodily relationship comparable to that existing between the secretory function of the gastric mucosa and the hematopoietic organs. This book contains a useful lesson for those who are inclined to minimize the importance of the gastro-intestinal tract in the general economy of the body, regarding it merely as a kind of test-tube in which the ingested food is prepared for absorption.

Digestion and Health. By Walter B. Cannon. Published by W. W. Norton & Co., New York, 1936, 160 pp. Price, $2.00.

IN this admirably written little book Professor Cannon discusses the relation of digestion to health. His treatise is based chiefly on the work performed by himself and his numerous co-workers. In the four chapters which form the main body of the text the author discusses: I. The nature of appetite and hunger; II. The nature of thirst; III. Digestion and bodily vigor; IV. Indigestion from pain, worry and excitement. There are also an Introduction and an Epilogue. Although the medical reader will doubtless be familiar with Cannon's theories concerning the peripheral origin of hunger and thirst sensations, the nervous regulation of gastro-intestinal motility and the "emergency" theory of adrenin secretion, he will find that the book records a great many new observations and experiments and that the author displays a profound understanding of the whole subject. The volume represents, in an expanded form, the lecture delivered by the author to the Wayne County Medical Society on the occasion of the centenary celebration in 1933 of the publication of William Beaumont's famous book, "Experiments and Observations on the Gastric Juice and the Physiology of Digestion" (Plattsburg, 1833). I am sure that practitioners will read Professor Cannon's book with delight and with great profit. Moreover doctors would do well to recommend it to patients suffering from gastro-intestinal ailments, for the sick man could thereby acquire a better understanding of the important part played by the alimentary canal in the whole economy of the body. In many cases this book would undoubtedly be more beneficial to the patient than any medicine.

B. P. Babkin, Montreal, Canada.

Program of the Fortieth Annual Meeting of the American Gastro-Enterological Association

JUNE 7TH AND 8TH, 1937

HOTEL CLARIDGE, ATLANTIC CITY

MONDAY, JUNE 7, 1937

MORNING SESSION, 9:15 A. M.
Daylight Saving Time

MEMORIAL ADDRESSES

of

Henry Plummer by George B. Eusterman
Sidney Simon by Daniel N. Silverman
Frank Smithies by Clement Jones

PRESIDENTIAL ADDRESS

Chester M. Jones, Boston, Mass.

1. The Influence of the Extrinsic Innervation on the Human Gastric Motor Mechanism
   Louis E. Barron, New Haven (by invitation)
2. Experimental Studies in Gastric Physiology in Man. V. Influence of Osmetic Tension in the Duodenum on Pyloric Action and Gastric Evacuation
   Harry Shay and (by invitation) J. Gershon-Cohen, Philadelphia
3. A Theory on the Formation of Peptic Ulcer
   Heinrich Necheles, Chicago

4. Massive Hemorrhage from Peptic Ulcer
   John M. Blackford, Seattle

5. Hemorrhagic Gastritis: A Gastroscopic Study

FELSEN, JOSEPH.

Acute and Chronic Bacillary Dysentery. Am. Jour. Path., XII, 3, p. 395, May, 1936.

A study based primarily upon the Jersey City epidemic of bacillary dysentery of 1934 is presented. The author's main purpose has been (1) to stress the fact that acute bacillary dysentery is a systemic disease in which the pathological lesions are caused by one or more toxins affecting, as well, extra-enteric organs; that the intestine alone need not bear the main brunt of the infection; and (2) that the late manifestations of the disease bear a very close relationship to non-specific ulcerative colitis.

It is believed that the intestinal lesions in the human are due to the excretion of the dysentery toxin, circulating in the blood stream, through the bowel wall. It is believed, too, that the toxin may be reabsorbed and repeat the cycle. The terminal ileum and colon seem to have a predilection for the toxin as the greater lesions are found there, although any portion of the bowel may be involved. An enteric and a neurotropic toxin have been isolated by Olitsky and Kligler. Clinical evidence exists which points to the presence of an arthritic and a myelotropic toxin also. The frequent association of labial herpes suggests, too, the presence of a virus. Examinations of the spinal fluid and the fluid from joints have failed to show the presence of microorganisms. In the chronic type of disease with arthritis, the acute dysentery infection having long before subsided, the joint involvement is probably due to a streptococcus or streptococcic toxin. The enterococcus is often recovered from the stools and other materials. A marked toxic granulocytopenia is at times observed. As the bone marrow in two cases coming to autopsy showed no evidence of deficiency in granulocyte formation, it was concluded the destruction of the leucocytes took place in the peripheral blood or in the vascular sinusoids of the bone marrow into which the granulocytes must migrate after their extravascular formation. Therefore the toxins of B. dysenteriae should be considered from the standpoint of selectivity as enteric, neurotropic, arthritic, and myelotropic. The Shiga-Kruse, Flexner, Hiss and Sonne-Duval strains all enter into the general picture.

The intestinal lesion in the acute dysentery begins as a definite hyperemia of the mucosa of large and small intestine with moderate edema and diffuse lymphoid hyperplasia of the solitary acuminate lymph nodules. Peyer's patches are similarly involved. The goblet cells pour out quantities of mucus, apparently for protection. On the second and third days blood oozes through the relatively intact epithelium. Superficial mucosal ulceration takes place—the lymph nodes become larger and central necrosis appears. The mild case usually does not extend beyond this stage. As the terminal ileum is severely affected patients have been on occasion operated upon for acute appendicitis—the mesenteric lymph nodes are then seen to be large, soft and pinkish in color. The acute stage usually subsides by the end of the third week. Continuing intestinal symptoms indicate chronicity and probably secondary non-specific intramural infection. The mucosa bleeds easily on examination, ulcers appear, and, as time goes on, the submucosa and deeper layers become involved, the wall thickened, haustration eliminated, pseudopolyposis may occur, etc.—the picture of chronic ulcerative colitis.

Follow up studies of cases of acute bacillary dysentery have shown that in some patients intestinal lesions persist long after the dysentery organism has disappeared from the feces. The longest period of observation was 4 years. In the Jersey City epidemic 122 cases out of a total of 210 hospitalized patients were examined 9 to 12 months after the acute attack; 18.8 per cent gave evidence of chronic ulcerative colitis. Epidemiological studies revealed definite contact and familial incidence in non-specific ulcerative colitis and a geographic districution corresponding to that of bacillary dysentery. Positive agglutination titers against B. dysenteriae were obtained in 62 consecutive cases of non-specific ulcerative colitis, in 2 of non-specific granuloma, and in 14 cases of chronic distal ileitis. Control studies of 300 serums showed diagnostic titers in 4.6 per cent.

The laboratory diagnosis depends upon: 1. fecal culture,—the specific dysentery organism is often isolated only during the first week; 2. diagnostic fecal bacteriophage; and 3. agglutination titer. The second begins to appear in the feces and the agglutination titer to rise in the blood after this time.

The character and modification of the dysentery toxins suggest that to be effective therapeutically, a specific serum must be used within the first few days when the major intestinal lesions occur. It should be an anti-toxin effective against known toxins that have been properly standardized by biological methods. Active immunization must be directed chiefly against the secondary non-specific invaders.

N. W. Jones, Portland, Oregon.

COLE, L. G.

The Pathological Yardstick. Its Accuracy as an Instrument for Measuring Errors in Clinical, Roentgenological, and Surgical Diagnosis of Gastric Lesions. S. G. O., Vol. 63, No. 6, pp. 689-716, Dec., 1936.

The author secured eight microscopic sections from seven organic gastric lesions and presented them to a group of representative and outstanding pathologists. Each pathologist was asked to state positively whether the lesion were a malignant one, and the type of malignancy if it were considered so. The criteria for each opinion were obtained for most of the pathological diagnoses given. If the pathologist were engaged in teaching, he was asked whether he would pass a student who could not differentiate a malignant lesion from a benign one. The answers to that question are not included in the paper.

In the answers received there was an incomprehensible diversion of pathologic opinion. In the study of some sections the pathologists were nearly equally divided in their opinions as to whether the lesion were malignant or benign. Among those who considered a particular lesion to be malignant there were some who diagnosed it as carcinoma, other diagnosed sarcoma, while others diagnosed lymphosarcoma. There was no unanimity of opinion concerning any one section. Of two sections made from the same specimen one was considered malignant by a large majority of the pathologists, while the other was considered benign by an equally large majority.

Certain of the pathologists when confronted with the results of this study made various remarks. Ewing under such circumstances remarked that there is no sharp line of demarcation between benign and malignant lesions. The author regards that as Ewing's most important and significant report.

The author believes that in studying a given section all the pathologists do not look at the same minute details of the section, others compare it to things they have seen before. Certain details do not mean the same thing to every pathologist and certain words have quite different meanings to different pathologists. Different lighting conditions and the degree of individual fatigue at the time the study is made are other factors which contribute to the truly incomprehensible diversion of pathologic opinion.

From this study the author has gathered a number of criteria by means of which neoplastic processes may be

differentiated from inflammatory ones. These will be reported at a future date. The effect of this difference of opinion among pathologists on the statistics of "surgical cures" and numerous other studies is obvious.

Eleven figures, three tables, a detailed account of each case, and each pathologists report accompany the article.

Nelson M. Percy, Chicago.

RIGLER, LEO G.

Leukemia of the Stomach Producing Hypertrophy of the Gastric Mucosa. J. A. M. A., Vol. 107, pp. 2025-2029, Dec. 19, 1936.

Generalized leukemic infiltration of the viscera, as well as of the bones, is not uncommon. Frequently it occurs with an aleukemic blood picture which may later change to a true leukemia.

The roentgen interpretation of this and similar conditions is bizarre, but exceedingly difficult to diagnose. The stomach usually shows a localized infiltration, often near the pylorus, with a marked constriction of the lumen of the stomach. There is also in many cases an elevation of the gastric mucosa throwing the rugae into large folas resembling the gyri of the brain.

The author presents two cases which roentgenologically resembled the above description but only one of them had characteristic findings of leukemia and responded to roentgen irradiation. He reached the conclusion that leukemia will produce a roentgen picture which is difficult to distinguish from other lesions, but which will change, or respond, to roentgen treatment.

Francis D. Murphy, Milwaukee.

DECOURCY, JOSEPH L.

Care of the Ruptured Appendix. Reduction of Mortality to Four Per Cent in Series of Fifty Cases. S. G. O., Vol. 63, No. 6, pp. 756-760, Dec., 1936.

The author quotes various statistics on the mortality of acute appendicitis showing how the mortality has increase from approximately 7 per 100,000 persons in 1900 to approximately 14 per 100,000 persons in 1933. He feels that this is not an entirely correct representation of the real truth.

Two avenues to lower the mortality of acute appendicitis are open to us: (1) the continuous and increasingly vigorous education of the public to the dangers of procrastination; (2) improved technical handling of the ruptured cases. Along the first avenue the need is obvious and well known.

It is along the second avenue that the author suggests an improvement. In a series of 50 cases of appendicitis with perforation, the author inserted a Pezzer catheter into the cecum after removing the appendix. That has served to decompress the colon, and has been useful as a means of instilling fluids into that part of the intestinal tract from which they are most readily absorbed. Later enemas and flushings of the bowel may be given through this catheter. The catheter usually begins to drain within twenty-four hours, and continues for 4 to 5 days. After the bowels act naturally the drainage from the catheter diminishes. The author does not state just when it is removed. Continuous gastric lavage by the continuous method as devised by Wangensteen is employed in certain cases. In this series of 50 cases the mortality was 4 per cent.

The author prefers the right rectus incision to the McBurney incision because it allows better access to the pelvis. In cases of appendiceal abscess the author feels strongly that any operation that does not remove the appendix is only a palliative measure and invariably invites sequels. By enlarging the incision, and carefully packing off the intestines, the appendix may be removed and the wound closed with or without drainage as the case may require.

The author believing that death in cases of ruptured appendicitis is due more to distention from intestinal obstruction than to infection, is of the opinion that the use of the Pezzer catheter will relieve the distention and lower the mortality of that condition.

Nelson M. Percy, Chicago.

GLENN, F.

Gastro-enterostomy. A Detailed Description of One Surgical Procedure. S. G. O., Vol. 63, No. 6, pp. 751-755, Dec., 1936.

The author presents in detail a method of making a gastro-enterostomy which, he hopes, will stimulate discussion which in turn will be followed by some progress in that field of surgery.

Pre-operatively the patient is fed on a high caloric diet and dental hygiene is instituted. The stomach is emptied twice daily in order to restore the normal elasticity of its walls and to reduce the number of bacteria in its contents.

The operative technique is the one originally described by Halsted. No clamps are used; all vessels are ligated with fine plain catgut. The opening through the mescolon should be to the left of the middle colic artery when possible. The site of the anastomosis on the stomach should be along an oblique line on the posterior surface of the prepyloric region. It should measure 10 centimeters in length. In selecting the site of anastomosis on the jejunum two points must be considered. The arrangement must be iso peristaltic and the loop of jejunum above the anastomosis must be long enough to prevent tension, yet not long enough to allow puddling of its contents. The proximal end of the stoma should be 10-15 centimeters from Treit's ligament. Silk sutures are used for the approximation of the serosa; No. 1 plain catgut is used as a suture through the entire thickness of the wall of the stomach and jejunum. The transverse mesocolon is attached to the gastric side of the anastomosis by means of interrupted silk sutures.

Postoperatively saline is given subcutaneously and glucose intravenously. Inhalations of carbon dioxide are given every two hours. If the patient is anemic a small blood transfusion may be given. The fluid intake is maintained at about 3000 c.c. daily. Nothing is given by mouth during the first two days, then small amounts of water and later albumin water, coddled egg and buttermilk are given. At the end of two weeks the patient eats a full variety of foods.

Postoperative vomiting may be controlled by gastric lavage. Pulmonary complications are avoided by frequently changing the position of the patient. It at the end of the second week the stoma is not functioning, operative correction of the fault may be necessary.

Six figures and a bibliography accompany the article.

Nelson M. Percy, Chicago.

DR. RIESMAN HONORED

Dr. David Riesman was guest of honor at a dinner on the evening of March 25, 1937, at the Bellevue-Stratford, Philadelphia, attended by more than 250 of his professional friends on the occasion of his seventieth birthday. Guest speakers included: Provost Josiah Penniman, Dr. Alfred Stengel, Dr. Henry A. Christian, Dr. Lewis A. Conner, Dr. Wilmer Krusen, Dr. William Gerry Morgan and Dr. Walter C. Alvarez. Dr. Russell Boles was toastmaster. Dr. Stanley C. Harris announced that friends of Dr. Riesman had made possible the publication of a volume of his selected writings to celebrate his birthday. An engraved plate, bearing the names of Dr. Riesman's former and present assistants, was presented by Dr. Thomas Fitz-Hugh, Jr. Dr. Riesman responded with a characteristically delightful account of his medical career and of his view of the present and future of medicine envisioned from the vantage point of his 'seventy year-high mountain-top."

SURGEONS WILL TAKE SCANDINAVIAN TOUR

New York, April. The Society of Clinical Surgeons, following their time-honored tradition of taking a trip abroad approximately every five years, will pay their first visit as a Society to Scandinavia this July. They have invited members of the Interurban Surgical Society, with their families, to join in the tour and the two groups will sail July 2 under Cook's auspices on the S. S. Gripsholm. They will visit the outstanding clinics of Denmark,

Sweden and Norway, which have been attracting much attention in recent years, and will combine scientific interest with the recreational and sightseeing features of a holiday abroad, continuing on to England and Scotland before returning to the United States.

The Society of Clinical Surgeons visited Great Britain in 1910, Germany in 1912, France, Italy, Austria and the Netherlands in 1925, and the British Isles again in 1930. This summer's Scandinavian Tour will cover Gothenburg, Copenhagen, Stockholm, Oslo, Ulvik, Stalheim, Voss and Bergen. Proceeding thence by steamer to Newcastle, the Society will round out its trip with visits to London, Edinburgh, the Trossachs and Glasgow, arriving in New York via the S. S. Caledonia, August 16.

Cook's conducted a similar trip last year for the Southern Society of Clinical Surgeons.

Preliminary Program of the Thirty-Eighth Annual Meeting of the American Proctologic Society

ATLANTIC CITY

Sunday, Monday and Tuesday, June 6, 7, 8, 1937

Headquarters: The Marlboro-Blenheim

Admission to the annual meetings is confined to members and such guests as are sponsored by members and thereafter invited by the Executive Council.

TENTATIVE SUMMARY OF EVENTS

SUNDAY, JUNE 6th—

Registration, The Marlboro-Blenheim	10:00 A.M.
Entertainment	2:00 P.M.

MONDAY, JUNE 7th—

Registration	8:00 A.M.
First Scientific Session	9:00 A.M.
Luncheon	12:00 Noon
Second Session	2:00 P.M.
Executive Session (for Fellows only)	8:00 P.M.

TUESDAY, JUNE 8th—

Third Scientific Session	8:00 A.M.
Luncheon and Round Table Conference	12:00 Noon
Fourth Session (Cancer Symposium)	2:00 P.M.
Annual Society Dinner (The Marlboro-Blenheim)—All registered guests invited	8:00 P.M.

WEDNESDAY, JUNE 9th—

AMA Section on Gastro-enterology and Proctology begins 3-day session	9:00 A.M.
AMA Section Dinner (The Marlboro-Blenheim) — All proctologists invited	7:30 P.M.

THE SCIENTIFIC PROGRAM—(Tentative)

Presidential Address: Problems and Progress of the American Proctologic Society. Dr. Marion C. Pruitt, Atlanta, Georgia.

Report of Committee on Arrangements: Dr. Homer L. Silvers, Atlantic City.

Memorial to Dr. Synott: The Secretary.

Review of the Literature of 1936: Dr. Warren R. Rainey, St. Louis, Mo.

CASE REPORTS

(Speakers are allotted five minutes and there is no discussion)

Ovarian Carcinoma Simulating Rectal Cancer: Dr. Martin S. Kleckner, Allentown, Pa.

Portable Sitz Bath for Rectal Cases: Dr. Cecil D. Gaston, Birmingham, Ala.

Rupture of the Intestinal Canal with Compressed Air: Dr. C. C. Neese, Wilmington, Delaware.

Tuberculosis of the Lungs, Cecum and Anus: Dr. Homer H. Wheeler, Indianapolis, Ind.

Neurofibroma of the Rectal Wall: Dr. Albert R. Keith, Hartford, Conn.

Diathermy Dilators for Rectal Stricture: Dr. F. M. Frankfeldt, New York City.

Adenocarcinoma of the Anus: Dr. Valentine R. Manning, Philadelphia, Pa.

Diverticulum of the Rectum with Fecal Impaction: Dr. Meyer H. Freund, New York City.

Rectal Carcinoma Associated with

Bile Salts *Without Phenolphthalein*

Neo-TaurocoL

Fulfills an Urgent Bile Salts Need

For those of the medical profession who desire to use a bile salts preparation without phenolphthalein we have produced NEO-TAUROCOL — which has already met with splendid response from the medical profession.

NEO-TAUROCOL is valuable in treating biliary tract disorders as well as effective in clearing up gastro-intestinal troubles preparatory to or as an adjunct treatment of fundamental disorders.

NEO-TAUROCOL is a combination of bile salts, extract of cascara sagrada and aromatics. It increases peristalsis, increases the flow of bile and stimulates the bile producing cells of the liver.

Other Plessner Products: Taurocol, Taurocol Compound with digestive ferments and Vera Perles of Sandalwood Compound.

Samples and literature sent on request.

THE PAUL PLESSNER COMPANY
DETROIT, MICHIGAN

A. J. D. D. 5-37

Uterine Sarcoma: Dr. Julius L. Werner, Philadelphia, Pa.

FORMAL PAPERS (15 Minutes)

Ileo-Colitis: Dr. Burrill B. Crohn, New York City. (By invitation).

The Place of Proctology Among the Surgical Specialties: Dr. M. S. Wolff, San Francisco. Discussion: Dr. Collier F. Martin, Philadelphia.

Perineal Hernia: Dr. Frank C. Yeomans, New York City. Discussion: Dr. Deseum C. McKenney, Buffalo.

Cod Liver Oil per Rectum as an Adjunct in the Treatment of Chronic Ulcerative Colitis: Dr. R. Russell Best, Omaha, Neb. Discussion: Dr. Walter A. Bastedo, New York City.

The Supra Levator Abscesses: Dr. H. Z. Hibshman, Philadelphia, Pa. Discussion: Dr. Louis J. Hirschman, Detroit.

Roentgen Aid to a Proctologic Diagnosis: Dr. C. C. Mechling, Pittsburg, Pa. Discussion: Dr. Alois B. Graham, Indianapolis.

The Management of Strangulated Hemorrhoids: Dr. Emor L. Cartwright, Fort Wayne, Ind. Discussion: Dr. Walter L. Fansler, Minneapolis.

Endometriosis of the Rectum and Sigmoid: Drs. James Schofield and Harry E. Bacon, Philadelphia, Pa.

SYMPOSIUM ON ANESTHESIA

Intravenous Anesthetic Agents in Proctology: Dr. Benjamin Haskell, Philadelphia, Pa.

Rectal Operations Under Local Anesthesia: Dr. Joseph H. Saphir, New York City.

Oil Soluble Anesthetics in Ano-Rectal Surgery: Dr. W. W. Green, Toledo, Ohio. Discussion: Dr. Marion S. Pruitt, Atlanta, Ga. Dr. F. B. Bowman, Hamilton, Canada. Dr. A. G. Carmel, Cincinnati, Ohio.

THE SYMPOSIUM ON CANCER OF THE RECTUM AND COLON

The Diagnosis of Rectal and Colonic Cancer: Dr. William H. Daniel, Los Angeles, Calif.

Selected Methods in the Treatment of Rectal Cancer: Dr. George E. Binkley, New York City.

The Treatment of Adenocarcinoma of the Rectum by Dessication: Dr. Edward G. Martin, Detroit, Mich.

Colectomy for Polyposis and Cancer of the Colon: Dr. Robert Scarborough, San Francisco, Calif.

The Rationale of the Surgical Technique in Carcinoma of the Rectum and Sigmoid: Drs. Jerome M. Lynch and G. Johnson Hamilton, New York City. Discussion: Dr. Louis A. Buie, Rochester, Minn. Dr. Thomas E. Jones, Cleveland, Ohio. Dr. Dan Jones, Boston, Mass. Dr. Dudley Smith, San Francisco, Calif.

Curtice Rosser, M.D., F.A.C.S.
710 Medical Arts Bldg.,
Dallas, Texas.

INTERNATIONAL CONGRESS ON HEPATIC INSUFFICIENCY

While the Universal Exhibition is being held in Paris, the International Congress on Hepatic Insufficiency will be in session at Vichy on the 16th, 17th and 18th of September, 1937, under the presidency of a member of the Academy of Medicine, Prof. Maurice Loeper of Paris. It will be divided into two sections:

(1) Medicine and Biology

(2) Medical, Surgical and Hydrological Therapy

Papers will be submitted in the two sections by the following gentlemen of different countries:

Medicine and Biology: K. Glaessner (Vienna): The Functional Diagnosis of Hepatic Insufficiency.

R. Debre, Gilbrin, Semelaigne (Paris): Enlarged Liver in Children.

Binet (Paris): The Sulphur Function of the Liver. The Edema Associated with Liver Dysfunction.

Lemaire and Varey (Paris): Pathogenical Study and J. Olmer (Marseilles): Clinical Study.

In over-eating, faulty diet or alcoholism...

IN gastro-intestinal toxemias, as well as in all forms of dyspepsia (other than those arising from gastric ulcer or cancer), the corrective influence of Vichy Celestins has long been recognized.

You can prescribe it with confidence wherever a natural still alkaline mineral water is indicated.

A valuable FREE booklet on the Therapeutic Value of Vichy with medical bibliography will be sent to any physician on request.

BOTTLED ONLY AT THE SPRING IN VICHY, FRANCE

AMERICAN AGENCY OF FRENCH VICHY, INC.
198 Kent Avenue, Brooklyn, N. Y.

VICHY CÉLESTINS

THE WORLD'S MOST FAMOUS NATURAL STILL ALKALINE WATER

Urbach (Vienna): The Skin and the Liver.

Parhon (Bucharest): The Liver and the Endocrine Glands.

Hamilton Fairley (London): The Stages of Hepatic Insufficiency in the Course of Malaria.

Therapy: Lathan A. Crandall (Chicago), A. C. Ivy (Chicago), Anthony Bassler (New York City), Norman Elton (Reading) and Hyman I. Goldstein (Camden): Hepatic Insufficiency in its Relations to General Nutrition and Especially to the Nervous System.

M. Brule (Paris): Hepatic Medications in Cases of Intolerance.

M. Villaret, L. Justin-Besancon, R. Cachera and R. Fauvert (Paris): Circulatory Insufficiencies and their Medications.

Piery and Milhaud (Lyons): The Hydro-Mineral Therapy of Hepatic Insufficiency.

DeGrailly (Bordeaux): Cellular Insufficiency and its Therapeutic Indications.

Gallart-Mones (Barcelona): Diet in the Restoration of an Impaired Liver.

Pribram (Berlin): Pre-operatory and Post-operatory Hepatic Insufficiency and its Preventive and Curative Treatment.

P. Duval, Gatelier, J. C. Roux, Goiffon (Paris): The Prognostic of the "Operative Crisis" by the Examination of the Hepatic Functions.

It may be recalled that this Congress will be preceded by the Second International Congress on Gastro-enterology, to take place in Paris on the 13th, 14th and 15th, September, 1937, under the presidency of Prof. Pierre Duval, at which two questions will be discussed:

(1) The Early Diagnosis of Cancer of the Stomach, under the presidency of Profs. P. Duval and Gosset of Paris, and of Prof. Konjetzny of Berlin.

(2) Acute and Chronic Occlusion of the Small Intestine: Authors have been selected in England, Belgium, Spain, the U. S. A., Italy and Poland for papers dealing with this latter question.

Those desiring to attend these Congresses may receive information by applying to Dr. Anthony Bassler, 121 East 71st St., New York City.

1937 GRADUATE FORTNIGHT OF THE NEW YORK ACADEMY OF MEDICINE

For the Annual Graduate Fortnight of The New York Academy of Medicine a subject of outstanding importance in the practice of medicine and surgery is selected and is presented from as many angles as possible. It offers to the profession a resume of the present knowledge of the subject so that the practitioner may be so informed.

The Tenth Annual Graduate Fortnight will be held November 1 to 12 and will be devoted to a consideration of Medical and Surgical Disorders of the Urinary Tract. The subject will include *Bright's disease, arterial* hypertension, and infections, tumors, calculi and obstructions of the urinary tract, and will exclude veneral disease, diseases of the genitalia and gynecology.

Twenty important hospitals of the City will present coordinated morning and afternoon clinics and clinical demonstrations. At the evening meetings prominent clinicians of New York and many of the other leading medical centers of this country who are recognized authorities in their special fields will discuss the several aspects of the general subject.

A comprehensive exhibit of books, pathological and research material, diagnosis, treatment and prevention whenever possible, clinical and laboratory diagnostic methods, X-rays, action of drugs and other therapeutic measures. Demonstrations will be held at regular intervals.

Some of the features to be presented

FOR THE CONVALESCENT

During convalescence, and for the restoration of strength, it is important that an easily digested food is provided. It is also desirable that food essentials be supplied in order to guard against a too restricted or unbalanced diet.

In HORLICK'S, extracted nutriments of the malted grains, combined with the full-cream milk contribute wholesome nutrition in a delicious and easily assimilated form. Bland in nature, low in residue, HORLICK'S puts little tax on the digestive mechanism, yet supplies a good proportion of carbohydrates, proteins, fat, calcium and phosphorus.

In addition, HORLICK'S
— has been dependable for half a century
— is a good source of natural milk and grain vitamins, notably A, B and G
— is clean and ready for use at all times

We Invite You to Listen to our Radio Program

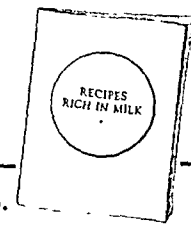
HORLICK'S MALTED MILK CORPORATION
RACINE, WISCONSIN

"Advice TO DRINK MORE MILK IS FUTILE . . .

*unless the milk is . . . . free from dangerous possibilities of transmitting infectious diseases"**

A simple truth, but an important fact—especially important in cases where digestive disorders may have created greater susceptibility to bacterial invasion.



Worthy of consideration in this connection is the fact that the use of Irradiated Pet Milk precludes the possibility of milk-borne infection. Sterilized in sealed containers, it is pure, double-rich milk completely free from bacterial life—as safe as if there were no germ of disease in the world.

Though its safety alone is a quality sufficient to recommend the inclusion of Pet Milk in the dietary for digestive diseases, its suitability is further enhanced by other virtues. Its ready digestibility is conducive to maximum nutrition with minimum intestinal irritation. Its altered antigenic factors better adapt it to the individual allergically sensitive to milk. Its extra amount of vitamin D, created by irradiation, promotes more efficient utilization of calcium and phosphorus.

Add to these the lower cost and it becomes quite obvious that Pet Milk possesses a combination of qualities unequalled by milk in any other form, strongly recommending its use in the dietary regimen employed in treating gastro-intestinal disorders.

Samples and literature will be sent on request.

To Successfully Re-Establish
Normal Regular Bowel Movement
Without Roughage...Without Irritant Drugs

- SAFE FOR Infants and Children
- SUGAR FREE Ideal For Diabetics
- A stable palatable emulsion of the Enzymes and Vitamins B-G of Brewers Yeast in 60% Pure Mineral Oil.

Only Teaspoon Dosage

ZymenoL Brewers Yeast Enzymes, through their catalytic activity in the upper and lower bowel, create and maintain a near fermentative field and favorable environment for beneficial bacteria.

Putrefaction is Checked. The intestinal bacterial flora is beneficially changed. The fecal mass becomes soft and bulky restoring peristalsis by natural impulse. Evacuation occurs daily with soft well formed stool, without gripe, purge or irritation.

Please write for samples

The following list of abstracts throw light on the vitamin value of canned foods:*

KOHMAN, E. F., EDDY, W. H. AND CARLSSON, VICTORIA.

Vitamin in Canned Foods. II. The Vitamin C Destructive Factor in Apples. 1924, Ind. Eng. Chem., 16, 1261.

Best modern canning practices for apples, allow the fruit to stand for some time in a 2 per cent salt solution in order to permit the removal of oxygen by respiratory processes. Apples cooked without the removal of oxygen suffer large losses of vitamin C. The vitamin C content of apples canned after removal of oxygen, compared favorably with that of the raw fruit.

SHERMAN, H. C., LAMER, V. K. AND CAMPBELL, H. L.

The Quantitative Determination of the Antiscorbutic Vitamin (Vitamin C). 1922, J. Am. Chem. Soc., 44, 165.

Filtered tomato juice, prepared from commercially canned tomatoes was used as the source of vitamin C in the experimental work. No symptoms of scurvy were found in guinea pigs receiving 3.0 ml. of this juice daily, as the sole source of vitamin C. It is concluded that commercially canned tomatoes are an excellent source of the antiscorbutic vitamin.

KOHMAN, E. F., SANBORN, N. H., EDDY, W. H. AND GURIN, CELIA ZALL.

Vitamins in Canned Foods. XIV. Calcium and Vitamin D in Foods. Ind. Eng. Chem., 26, 758, 1934.

Rats were carried through five generations on the following diets: a mixture of raw foods, the same mixture home cooked, and a similar mixture of

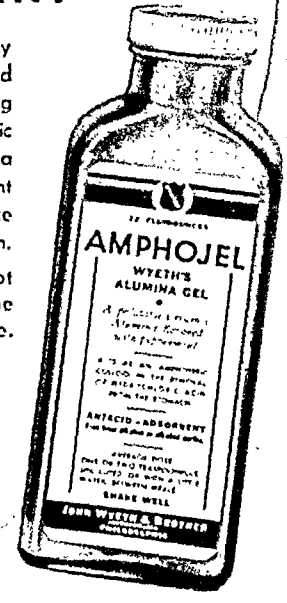
Control gastric hyperacidity without the use of alkalies!

AMPHOJEL

Wyeth's Alumina Gel

ANTACID—ADSORBENT



Amphojel, Wyeth's Alumina Gel, is a creamy palatable colloidal suspension of hydrated alumina—$Al_2(OH)_6$—capable of neutralizing in one hour not less than 12 volumes of gastric juice containing 0.36% hydrochloric acid. Thus, a teaspoonful will neutralize to Toepfer's reagent over one and one-half fluid ounces of such juice or a corresponding amount of stronger secretion.

Even excessive use of Amphojel will not cause gastric alkalinity, altered pH of the blood stream or secondary acid rise.

Indicated for the control of gastric hyperacidity

•

JOHN WYETH & BROTHER, Inc., PHILADELPHIA

commercially canned products. With rate of growth, weight of young at birth and weaning, number of deaths before weaning, and per cent ash of the tibia used as the means for comparison, the canned food diet was found to be superior to either the raw or home cooked diet.

The addition of milk or calcium salts to a mixture of five common foods produced an increase in ash content of the tibia. Addition of cod liver oil to a diet of canned foods, along with calcium salts added to give the calcium phosphorus ratio of the Steenbock rachitogenic ration, did not produce a further increase in bone ash.

Experiments reported by the authors demonstrate that ordinary foods contain a significant amount of vitamin D, and that most foods are deficient in calcium. The better performance of rats on the canned food diet was believed to be due to a greater availability of a limited calcium supply.

WHEELER, G. A.

The Pellagra-Preventive Value of Autoclaved Yeast, Canned Flake Haddock, and Canned Green Peas. U. S. Public Health Reports, 48, 67, 1933.

The food studied was fed as a supplement to a basic diet which was known to produce pellagra in the human. Regular commercial products were used in these studies.

Canned flake haddock at the rate of 227 grams daily did not prevent the occurrence of certain symptoms of pellagra. Daily portions of 340 grams protected women from all traces of this disease. These findings demonstrate the value of canned haddock in the prevention of pellagra.

Announcing:

Gerber's

Liver Soup With Vegetables

A New Product Meeting a Dietetic Requirement

We've added Gerber's Liver Soup to the Gerber family because of the most insistent demand we've ever had for a product—a demand which came largely from doctors!

In this fine soup, intended especially for use with infants, children and adults' special diets, Gerber combines beef liver, carrots, potatoes, lima beans, celery, tomatoes, onions, barley, wheat germ and salt. When liver is introduced into a low iron-content diet (the usual milk, sugar and cod liver oil diet of infants) there is an increased retention of iron. To the adult requiring a fibre-free diet, Gerber's Liver Soup is excellent because it provides all the benefits of liver without the fibre. Furthermore, it is very palatable.

As in all Gerber products, Gerber scientific methods of straining and cooking, in absence of air, with the evaporation of excess moisture, make possible a high conservation of beneficial properties.

DEVANEY, GRACE M. AND PUTNEY, LYDIA K.

The Vitamin A and D Content of Canned Salmon. J. Home Econ., 27, 658, 1935.

Two to four brands each of Chum, Pink, Red, and Chinook salmon purchased on the retail market, were examined for vitamin A and D potency. The liquid in the cans as well as skin and bone were removed before feeding. The vitamin A and vitamin D contents of the various brands expressed in International units are given in the following table:

Vitamin Content of Salmon

Variety	International Units of Vitamin A per Gram	International Units of Vitamin D per Gram
Chinook	8	3.9
	4	2.6
		2.1
Red	4	8
	2.5	
Pink	1	7.1
	1	7.8
		6.2
		4.0
Chum	0.5	2.6
		1.9

These data indicate that Chinook and Red salmon are richest in vitamin A. Red and Pink varieties are the best sources of vitamin D. Of the foods commonly included in the diet, canned salmon is one of the richest sources of vitamin D. In addition to vitamins A and D canned salmon supplies an inexpensive protein of excellent biological value.

EDDY, W. H., GURIN, CELIA ZALL AND KOHMAN, E. F.

Vitamins in Canned Foods. XII. Supplementary Nature of Grapefruit and Prunes. Ind. Eng. Chem., 24, 457, 1932.

The vitamin C contents of raw and canned grapefruit were compared by means of guinea pig feeding tests. Three grams per day of either the fresh or canned fruit fully protected guinea pigs from scurvy, and only mild symptoms of scurvy were found in guinea pigs receiving a two gram dosage.

Hepatic Lesions Presumably Secondary to Pancreatic Lithiasis and Atrophy; Report of Two Cases

By

ALBERT M. SNELL, M.D.*

and

MANDRED W. COMFORT, M.D.*

ROCHESTER, MINNESOTA

PHYSIOLOGISTS have long been aware that depancreatized animals maintained with insulin and dietary regulation alone are liable to develop hepatic insufficiency due to infiltration of the liver with fat. Ivy, in a recent discussion of the physiology of the pancreas, raises the question whether such changes ever occur in human subjects and states that to his knowledge they have not been observed. We have recently had under observation a young man with pancreatic lithiasis, diabetes mellitus, and steatorrhea which has been proved to be due to complete absence of the external pancreatic secretions; he apparently has complete, or nearly complete, pancreatic insufficiency. His case is of particular interest because of the late and rather sudden development of secondary changes in the liver which are presumably comparable to those which have been described in the experimentally pancreatectomized animal. In addition, two other patients with chronic pancreatic disease have been seen at the clinic, apparently with similar changes in the liver. We propose to report these cases and to summarize the available information on the subject of hepatic lesions which may be secondary to pancreatic disease.

The usual sequelae of pancreatectomy in the dog are well known and require only brief consideration. Fisher (1924) was the first to show that while pancreatectomized dogs could live as long as eight months with insulin and dietary care, all of them succumbed eventually to a condition other than diabetes. The usual, and often the only, postmortem finding of significance was marked enlargement of the liver with an extreme degree of fatty degeneration. Allan, Bowie, MacLeod, and Robinson published a report which confirmed Fisher's findings in the same year, noting that shortly after pancreatectomy there was deposition of fat in the liver, which cleared under treatment with insulin, and that a second fatal episode of fatty degeneration which was unaffected by dietary regulation or insulin occurred later in the course of the experiment. At necropsy of some of these animals the liver was found to contain as much as 20 per cent fat by weight. When raw pancreas was added to the diet, fatty change in the liver was to a great extent prevented.

In 1932, Best and Hershey reported their studies on the subject, especially from the standpoint of the effect of fatty degeneration of the liver on carbohydrate metabolism. When hepatic insufficiency developed in their animals, weakness, loss of weight and anorexia were the first symptoms; the dogs later became slightly jaundiced and glycosuria diminished gradually on a constant diet, so that, finally, little or no sugar was found in the urine. If lecithin was added to the diet, it was found that it prevented fatty deposition and maintained the animals in good condition; biopsy specimens of the liver did not contain deposits of fat, while glycosuria was increased to its original level. Later (1933), Best, Ferguson, and Hershey demonstrated by direct and indirect methods that choline, an important component of lecithin, also prevented the deposition of fat in the liver. Dragstedt and his associates (7, 15) (1936) have reported their studies on the relation of pancreatic activity to fat metabolism. They showed that fatty degeneration of the liver is not primarily due to loss of pancreatic secretions in the digestive tract and that the condition is not relieved by the oral administration of pancreatic juice. They have demonstrated further that the pancreas contains a substance which on administration by mouth prevents the deposition of fat in the livers of pancreatectomized dogs. This substance, which they have named "lipocaic," is presumably a hormone with a regulatory effect on the deposition and metabolism of fat.

If these studies on animals can be applied clinically, it seems reasonable to suppose that fatty degeneration of the liver might develop when there was sufficient pancreatic damage to produce more or less complete pancreatic insufficiency, and that the process might reasonably be expected to respond to the administration of lipocaic. We believe such a condition existed in our first case.

REPORT OF CASES

Case 1. The patient, a mechanic, aged thirty-six, was observed over a period of about two years. He was of reasonably good habits, but admitted that he drank to a moderate extent. At the age of twelve years he had had biliary colic followed by jaundice; no further details of this illness are available. At the age of twenty-eight he began to suffer attacks of severe upper abdominal pain which was projected bilaterally, more to the left than to the right, and which also extended to the back. Repeated injections of morphine always were necessary for relief. At the age of twenty-nine, abdominal exploration was performed because of the suspicion of a penetrating or perforating peptic ulcer; no ulcer was found but the operating surgeon noted induration of the pancreas. Between the ages of twenty-nine and thirty-six, the patient continued to have attacks of severe abdominal pain at frequent intervals, usually followed by vomiting and sometimes by diarrhea. Six weeks before the time of his first admission to the clinic in the spring of 1935, diabetes mellitus developed which was severe from the onset; about

No Other Special Medical Journal Ever Made the Subscription Showing in 3 Years That Has Been Accorded to the American Journal of Digestive Diseases and Nutrition

With only the numerically small American Gastro-enterological Association as a formal backer, this Journal has independently attracted a record group of constant readers.

WHY? . . . .

The reasons are obvious—

- One of the strongest Editorial groups in American Medical Journalism, realizing the void that existed in gastro-enterological literature, determined to make a special Journal that would meet very specific needs.
- The needs were for a journal that would collect and attract under one head the important contributions in this field, thus enabling the reader to learn what he wished without the inconvenience of looking through an extensive literature.
- This has been done . . . today our Editor receives countless manuscripts from the investigators of the U.S.A. . . . today numerous readers volunteer the fact that they have never made better investments than in the Volumes of the American Journal of Digestive Diseases and Nutrition.

Spend $6.00 per year or $10.00 for two years NOW.

Join the increasing Group of doctors, whose enthusiasm has made and is making history in American Medical Journalism.

The card below is attached for your use and is postage free.

CREAM OF WHEAT

When Diet Itself *Becomes a Therapeutic Factor*

In many affections of the gastro-intestinal tract, and during the course of numerous infectious diseases, diet often assumes equal importance with specific therapy. In such cases, Cream of Wheat is especially valuable. When cooked, it consists of soft, non-irritating wheat granules which are mechanically bland and evoke a minimum flow of acid gastric juice. Furthermore, Cream of Wheat is high in nutritional value, an ounce yielding 115 calories of quickly assimilated food energy.

Because of these physical and chemical properties, Cream of Wheat finds an important place in the dietaries of patients afflicted with peptic ulcer, the various dysenteries, colitis, and as a rapidly available source of energy in infectious diseases and convalescence.

THE CREAM OF WHEAT CORPORATION

MINNEAPOLIS, MINN., U. S. A.

The vitamin C content of canned grapefruit, one of the best sources of this vitamin, is substantially that of the raw fruit.

Rats receiving 3 to 7 grams of raw or canned grapefruit as a source of vitamin A failed to grow. This fruit contains no appreciable quantity of vitamin A.

Raw and canned grapefruit contain both vitamins B and G in rather limited quantities. They appear to contain slightly more vitamin G than B.

The vitamins in grapefruit are apparently stable under the conditions existing in the commercial canning procedure.

CLOW, BERTHA, PARSONS, HELEN T. AND STEVENSON, INA.

The Vitamin C Content of Commercially Canned Sauerkraut Together with Some Observations on Its Vitamin A Content. J. Agr. Res., 41, 51, 1930.

Two brands of commercially canned sauerkraut were found to protect guinea pigs from scurvy if fed at the rate of 5.0 grams daily. This was the protective dosage found for a sample of raw sauerkraut. Four other brands of canned sauerkraut were found to be less potent sources of vitamin C. The least potent brand contained 1/3 to 1/2 as much vitamin C as the most potent brand. The six brands of sauerkraut examined were packed from different samples of cabbage and under different conditions; therefore, the factors responsible for the variations in vitamin C content were not determined. These data would indicate that while the antiscorbutic potency of canned sauerkraut may be variable, the product definitely contributes vitamin C to the diet.

The contribution of vitamin A by stored winter cabbage or canned sauerkraut is negligible.

KOHMAN, E. F., EDDY, W. H. AND GURIN, CELIA ZALL.

Vitamins in Canned Foods. XI. "A Canned Food Diet." Ind. Eng. Chem., 23, 1064, 1931.

White rats and guinea pigs were fed *ad libitum*, a diet composed of five canned foods selected to give a balanced diet. The combination of foods was changed every five days so as to include a wide variety of canned products in these tests.

Forty-nine commercially canned foods, purchased on the retail market, were fed in seventy-four combinations. No supplements of any kind were added to the diet; neither were the animals exposed to sunlight. In fifteen months, the experimental rats had reached the fifth generation. Rate of growth, reproduction, and lactation were normal in all respects in all generations, indicating that the canned food diet had adequately met all nutritive requirements.

A similar experiment, carried out with guinea pigs, resulted in normal growth, reproduction, and lactation through three generations in thirteen months. These experiments demonstrate that a diet composed exclusively of commercially canned foods meets the nutritional requirements of rats and guinea pigs during the complete life cycle. The significance of these results in human nutrition is that canned foods may be depended upon to supply in good degree the vitamins present in the raw foods from which they were prepared.

WHEELER, G. A.

The Pellagra-Preventive Value of Autoclaved Yeast, Canned Flake Haddock, and Canned Green Peas. U. S. Public Health Reports, 48, 67, 1933.

The pellagra-preventive value of commercially canned peas was investigated. Canned green peas were fed as a supplement to a basic diet which was known to produce pellagra in women. Daily allowances of 450 grams of this vegetable protected women from the disease during a year.

Toxic Absorption From the Bowel

● It is recognized that many symptoms in themselves far removed from the bowel, are the direct result of toxic absorption from the intestinal tract.

Soricin has been used with most gratifying results for detoxification of the intestinal content. Urticaria, angioneurotic edema, headache, vertigo, certain forms of eczema and other conditions when known to be caused by toxic absorption, have responded to the continued oral administration of Soricin over a reasonable period of time.

Clinical sample and additional literature to physicians on request.

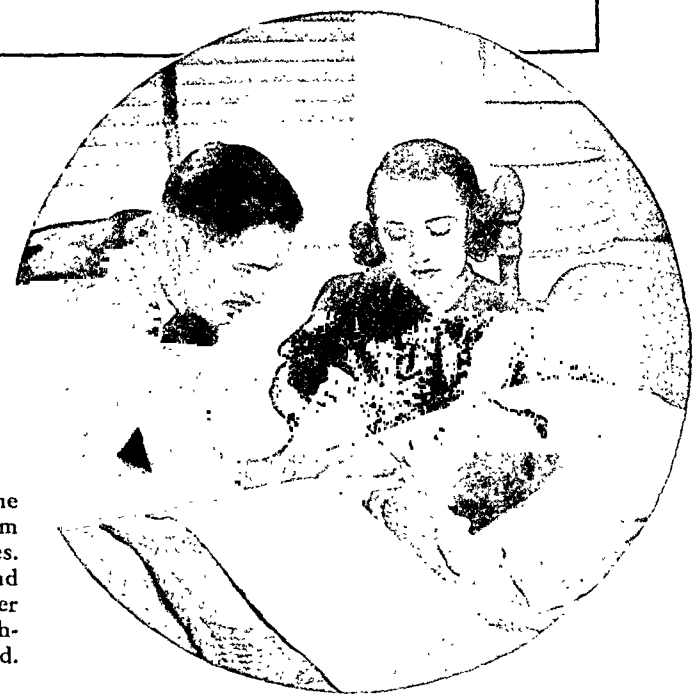
Soricin

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate available in five-grain and ten-grain sizes.

Soricin Tablets—Enteric coated tablets, each containing five grains of sodium ricinoleate.

Soricin and Bile Salts Tablets—Enteric coated tablets, each containing four and one-half grains of sodium ricinoleate, and one-half grain of bile salts.

ACTION: Detoxifies in vivo • Desensitizes • Inhibits putrefaction • Prevents toxic absorption.



INDICATIONS: Bacterial Hypersensitivity of the intestinal tract • Intestinal toxemia • Intestinal allergy • Allergic diarrhea • Urticaria—angioneurotic edema • Colitis.

Literature and Sample on Request

THE WM. S. MERRELL COMPANY, Cincinnati, U. S. A.

DURING CONVALESCENCE

...when resistance is low

Diet plays an important part in the convalescence of children from colds and other Spring illnesses. This is because appetite and digestion are frequently under par and the demand for nourishing, building food is increased.

Reinforce the Ordinary Diet . . .

There is one food supplement which fulfills all the requirements of the convalescent dietary regimen. Originated for this *very* purpose, it is called Ovaltine. Highly nourishing and palatable, it is a food that is well rounded and easily tolerated. It not only tempts the taste, but can actually stimulate the lagging appetite of the convalescent child. A wide variety of "protective" food elements are found in Ovaltine. Easily prepared, it is well adapted to between meals feedings. Children are delighted with this treat and welcome it as an addition to their diet.

Why not recommend the use of Ovaltine at meals and between meals during the convalescent period? It can be of great value in helping to shorten convalescence, especially in children. Try it and see for yourself.

• • •

You may have some convalescent child in mind right now. If so, we will send you prepaid a large can of Ovaltine. Send evidence of professional standing to The Wander Company, 360 North Michigan Avenue, Chicago, Ill. Copr. 1937, The Wander Co.

D. N. 5

Canned green peas are a valuable source of the pellagra-preventive factor.

WHEELER, G. A.

The Pellagra-Preventive Value of Canned Spinach, Canned Turnip Greens, Mature Onions and Canned Green Beans. U. S. Public Health Reports, 46, 2663, 1931.

Daily portions of 482 grams of commercially canned spinach was the source of the pellagra-preventive factor in the diet of 14 women. Thirteen of these women developed no symptoms of pellagra during a year, while one showed signs of the disease near the end of eleven months on the diet. These data demonstrate that canned spinach could well be included in the diet for the control of pellagra.

PARSONS, HELEN T. AND HORN, CAROLYN.

The Vitamin C Content of Commercially Canned Sauerkraut Produced Under Known Conditions. J. Agr. Res., 47, 627, 1933.

Four brands of sauerkraut produced under conditions as nearly identical as possible were examined biologically for vitamin C. One brand protected guinea pigs from scurvy when fed at the rate of 5 grams daily. The other brands were not such potent sources of vitamin C.

Cabbage was reported to be protective in daily doses of 2.5 to 5 grams, but, since this was not the same material from which the sauerkraut was prepared, direct comparisons can not be made.

Canned sauerkraut is considered a valuable source of vitamin C.

KOSITZA, LILLIAN.

A Comparative Study on the Use of Unsweetened Evaporated Milk and Bottled Cow's Milk in Infant Feeding. J. Pediatrics, 1, 426, 1932.

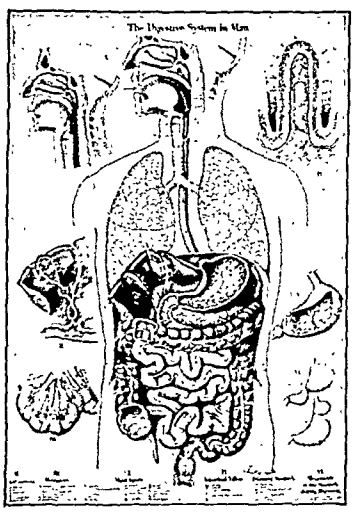
A group of 217 infants were studied by physicians at the Los Angeles City Welfare Conference. Of 217 normal feeding cases, 110 were given unsweetened evaporated milk and 107 were given bottled cow's milk. The formula of the unsweetened evaporated milk approximated that of bottled cow's milk. Supplements of vitamins A, C and D were given in the form of orange juice, tomato juice, and cod liver oil.

Observations were made upon 13 premature infants, 8 of which were given unsweetened evaporated milk and 5 bottled cow's milk.

Slightly larger gains in body weight made by infants given unsweetened evaporated milk, than by infants given bottled cow's milk. The increase in height of the infants on the two milks were about equal. Diarrhea was not as frequent in infants receiving unsweetened evaporated milk as in those receiving bottled cow's milk. Incidences of constipation were just about the same in the two groups. Infants fed unsweetened evaporated milk vomited a little more frequently. Aside from weight increases there were no appreciable differences in the performances of infants fed unsweetened evaporated milk and those fed bottled cow's milk.

From the standpoint of economy, availability, sterility, uniformity of composition, and ease of digestibility unsweetened evaporated milk has decided advantages over bottled cow's milk for infant feeding.

RICE, FRANK E.



Protein, Minerals and Vitamins of Evaporated Milk. Am. J. Public Health, 24, 194, 1934.

The nutritive value and uses of evaporated milk are reviewed.

The heating of milk during evaporation brings about changes in its chemical, physical, and physiochemical properties. Due to these changes a finer curd is formed by the action of rennin or acid upon evaporated milk than upon raw milk. Protein, calcium, and phosphorus of evaporated milk, on a comparative basis with other forms of cow's milk are well utilized.

The vitamin A, D, or G content of milk is not affected by the processes of

A STRIKING ACHIEVEMENT

WINTHROP

BETAXIN

TRADEMARK

The synthetic production of vitamin B_1 in pure form represents a distinctive chemical achievement. Vitamin B_1 is recognized as a dietary essential for infants, children and adults.

The first synthetic vitamin B_1—Betaxin—makes available to physicians an adequate and economical supply of this dietary essential and antineuritic factor. According to clinical reports vitamin B_1 is indicated not only in *beriberi*, but also in less severe B_1 avitaminosis characterized by *anorexia, gastric and intestinal atony*. Its use is also suggested in pregnancy and lactation, when metabolism is increased, as in hyperthyroidism and infections, and in various nervous disorders of nutritional origin.

●

How Supplied: For oral administration tablets of 0.1 mg. and 1 mg., bottles of 50; for intramuscular injection, ampules of 1 cc. (= 1 mg.), boxes of 10. For research laboratories, crystals in vials of 15 mg. and 50 mg.

Each milligram is equivalent to 500 international units.

evaporating and canning. These processes reduce vitamin B content by about one-fifth, and vitamin C content to a considerable extent. The losses are not serious, however, because milk is not an important source of these vitamins and the diet should be supplemented with foods rich in them.

Evaporated milk diluted with an equal volume of water gives, at a very reasonable cost, a sweet milk for every use. The flavor of evaporated milk differs from that of the raw product; but, as with pasteurized milk, one becomes accustomed to the new flavor and develops a positive liking for it.

Its freedom from pathogenic organisms, ready digestibility, uniformity of composition, and economy recommend evaporated milk for infant feeding.

Report of Annual Meeting of Council on Pharmacy and Chemistry. J. Am. Med. Assn., 102, 1299, 1934,

The annual meeting of the Council on Pharmacy and Chemistry of the American Medical Association adopted the following units and standards for vitamins A and D.

Vitamin A

One unit U. S. P. X. (Revised 1934) = one unit International.

One unit U. S. P. X. (Revised 1934) = 0.714 unit U. S. P. X. (1925).

Vitamin D

One unit U. S. P. X. (Revised 1934) = one unit International.

One unit U. S. P. X. (Revised 1934) = 3.26 units A. D. M. A.

One unit U. S. P. X. (Revised 1934) = 0.37 unit Steenbock.

To be acceptable for inclusion in New and Non-official remedies, cod liver oil must contain not less than 850 units U. S. P. X. (Revised 1934) of vitamin A and 85 units U. S. P. X. (Revised 1934) of vitamin D per gram. The average recommended daily dose is, for infants, 12 ml. and for adults 24 ml.

To be acceptable, cod liver concentrates must contain at least 1,100 U. S. P. X. (Revised 1934) units of vitamin A, and 110 U. S. P. X. (Revised 1934) units of vitamin D per capsule or other dosage unit.

GOLDBERGER, JOSEPH AND WHEELER, G. A.

A Study of the Pellagra-Preventive Action of the Tomato, Carrot, and Rutabaga Turnip. U. S. Public Health Reports, 42, 1299, 1927.

Six ounces of juice from canned tomatoes were not effective for the prevention of pellagra; however, a daily dose of 40 ounces was effective for preventing pellagra in 18 women for over a year. The authors point out that their earlier idea about the lack of the pellagra-preventive in tomato juice was erroneous due to an unjust appraisal of the factor of quantity.

In Your Next Ulcer Case

With your next case of peptic ulcer, Doctor, consider Creamalin, the distinctive colloidal cream of aluminum hydroxide that has revolutionized the treatment of gastric and duodenal ulcer. Note its superiority and advantages:

Prompt Symptomatic Relief

Pain and epigastric discomfort disappear promptly. Reduction of acid irritation of the ulcer bed, together with correction of pylorospasm and hyperperistalsis, insure the patient's comfort.

Dependable Acid Fixation

Creamalin fixes by adsorption 12 times its volume of N/10 HCl in less than 30 minutes. Acid neutralization is complete, sustained, constant.

No Secondary Acid Rise
No Change in Blood pH

Creamalin does not induce secondary secretion of HCl, as do the soluble alkalies. Since it is not absorbed into the bloodstream, it produces no change in the blood pH or acid-base balance — hence alkalosis cannot occur.

Rapid Demonstrable Healing

With Creamalin Therapy (continuous drip) all roentgenologic evidence of the ulcer disappears in 7 to 12 days, under oral administration in 3 to 6 weeks. Gastric and duodenal ulcers yield with equal rapidity.

A sample of Creamalin and reprints of published reports await your request.

Cleveland Chemical Associates

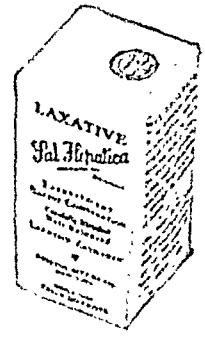
(3rd of a SERIES)

Salines . .

in Atonic Constipation . . .

When the retarding mechanisms of the colon are too prolonged, mass movements fail and abnormal desiccation occurs, causing constipation of a type relieved by salines.

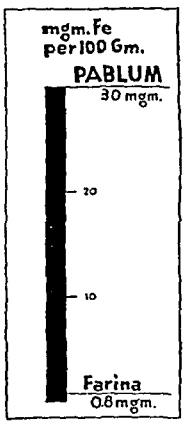
Sal Hepatica



the mild saline aperient, offers essentially the same action as achieved by certain famous mineral waters. It helps to perform the two-fold function of waste elimination and alkaline conservation.

New experimental evidence indicates that Sal Hepatica stimulates an increased rate of bile flow from the gall bladder into the duodenum.

Sal Hepatica helps to combat tissue plasma acidity and to prevent mucous colitis resulting from retention of dry, irritating fecal masses. Support the disease-resisting factors of the body and eliminate waste material with Sal Hepatica. Send for samples and literature.



Sal Hepatica Flushes the Intestinal Tract and Aids Nature to Combat Acidity

BRISTOL-MYERS CO.
19-NN WEST 50th STREET
NEW YORK, N. Y.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than farina in iron and in calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation. Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embyro, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

SEBRELL, W. H.

Table Showing the Pellagra-Preventive Value of Various Foods. U. S. Pub. Health Rpts., 49, 754, 1934.

The pellagra-preventive value of various foods which have been thoroughly tested under controlled conditions in both dogs and humans are tabulated. Pellagra-preventive values are assigned on the basis of amounts fed; good indicating absence of pellagra in all subjects, fair signifying appreciable to considerable pellagra-preventive value with evidence of pellagra in one or more subjects, slight denoting the failure to prevent the disease but delaying onset and, none indicating the absence of pellagra-preventing value of practical importance.

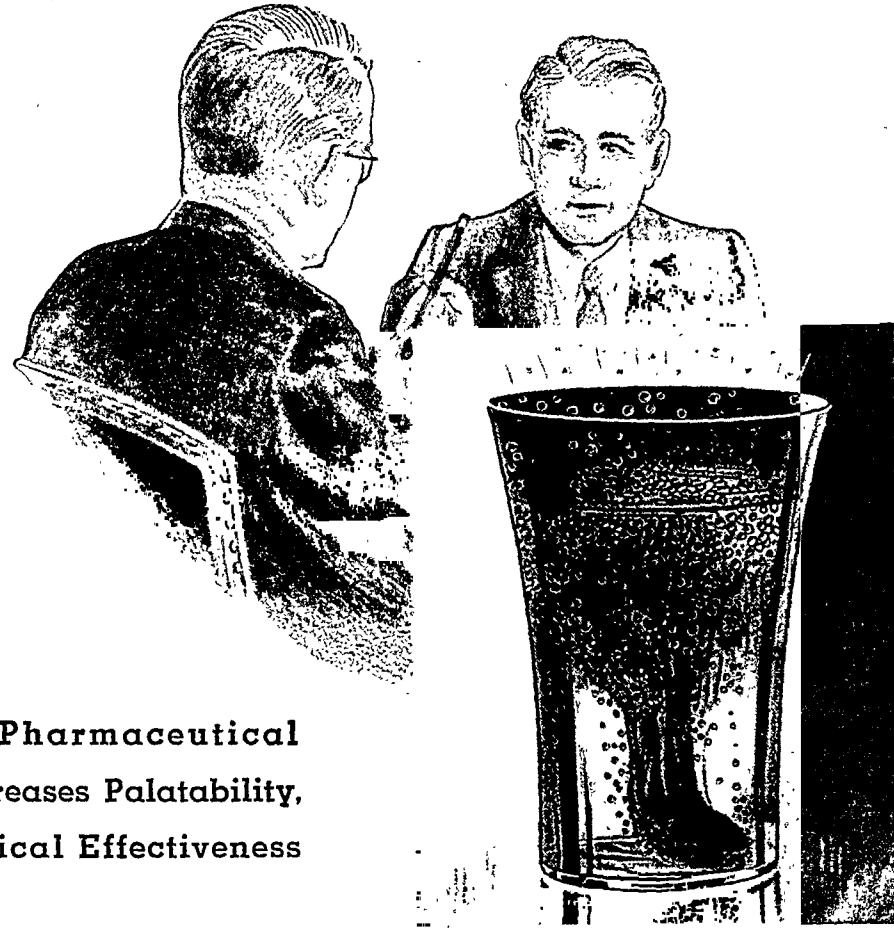
Canned Food	Daily Amount (Grams)	Pellagra-Preventive Value
Beef, Corned	200	Good
Chicken	325	Good
Salmon	168	Good
Collards	482	Good
Kale	534	Good
Peas, Green	450	Good
Tomatoes, Juice from	1200	Good
Turnip Greens	482	Good
Haddock	340	Fair
Evaporated Milk...	15 c.c. per kilo of body weight	Fair
Cabbage, Green ...	482	Fair
Mustard Greens ...	533	Fair
Spinach	482	Fair
Beans, Green Stringless	550	Slight
Lettuce, Cos	516	Slight
Onions, Green	502	Slight

CALDWELL, G. W.

The Nutritive Value of Strained Vegetables in Infant Feeding. J. Pediatrics, 1, 749, 1932.

Pediatricians appreciate the value of foods rich in minerals and vitamins in the diets of young infants. In the past there has been some uncertainty as to the ability of young infants to digest, absorb, and tolerate supplements of vegetables.

In a series of experiments, strained vegetables were fed to 60 infants. The amounts fed daily were, 1 ounce up to 3 months, 2 ounces from 3 to 5 months, and 4½ ounces from 5 to 9 months. The strained vegetables were well tolerated by the majority of infants. The infants were practically free from digestive disturbances, in only 8 cases were the stools loose, and in these cases for only 2 to 4 days. Two infants vomited one feeding a day for one month.



The results indicated that the feeding of strained vegetables contributed to the physical development and well being of the infants.

Properly prepared strained vegetables included in the diet aid in supplying adequate amounts of minerals and vitamins to assist in the promotion of optimum development of bone and teeth. Modern scientific methods enable manufacturers to prepare strained vegetables "in such a manner as to retain" a large portion of the essential minerals and vitamins.

KOHMAN, E. F.

Stabilizing Nutrients by Canning. Ind. Eng. Chem., 24, 650, 1932.

This paper is a general discussion of the contribution of the canning industry to present day problems arising from changing dietary demands. Fruits and vegetables are harvested at the proper stage of maturity when nutritive values are at a maximum and canned shortly after harvesting. Modern canning practices tend to preserve rather than diminish the inherent nutritive values which are rapidly lost upon storage in the raw state.

An Improved Pharmaceutical Form Which Increases Palatability, Tolerance, Clinical Effectiveness

Effervescence . . . Buffered Alkali

Applied to

ASPIRIN . . . ASPIR-VESS offers a convenient, palatable and an unusually effective method of administering aspirin in combination with alkali buffer salts.

Physiologic Correction
for Your Cathartic Addicts

Cholmodin effectively interrupts the vicious cycle of habituation to irritant laxatives. With Cholmodin, the annoying habit may be corrected, since its composition of deoxycholic acid and extract of aloes affords a means of correcting chronic constipation in a physiologic manner. The bile acid derivative restores normal tonus in the small intestines, as well as increasing peristaltic activity; the extract of aloes effectively activates the colon. Thus the entire tract is stimulated to normal function. After an appropriate period of therapy evacuation occurs spontaneously.

REG. U.S. PAT. OFF.

This conservation of nutrients is effected by one or more of the following factors: removal of oxygen by preheating, rapid heating to produce ebullition of occluded gases and use of vacuum. It is concluded that vitamins A, D, and G are not destroyed during canning and that vitamins B and C are less liable to the canning procedure than is generally believed. Commercial canning serves an important function in stabilizing vitamins in perishable foods for year round consumption.

TOLLE, C. D. AND NELSON, E. M.

Salmon Oil and Canned Salmon As Sources of Vitamins A and D. Ind. Eng. Chem., 23, 1066, 1931.

The vitamin A and D content of commercially canned salmon of five different species was determined by biological assay using albino rats. The oil was expressed from the canned product and fed in graded doses.

Vitamin A potency was not found to be high and it varied directly with the degree of pigmentation. Oil from two species of canned salmon had vitamin D potencies equal to that of medicinal cod liver oil, while a third species was found to be about one-half as potent.

From a consideration of the vitamin D values of salmon oil, the oil content of canned salmon and the quantity of canned salmon consumed annually in this country, it was concluded that this product supplies more vitamin D than the cod liver oil used for both human and animal feeding.

GOLDBERGER, JOSEPH AND WHEELER, G. A.

A Study of the Pellagra-Preventive Action of Canned Salmon. U. S. Public Health Reports, 44, 2769, 1929.

A moderately priced grade of commercially canned salmon (Alaska chum) was demonstrated to be a good source of the pellagra-preventive factor. Six ounces per day protected women from pellagra. Experiments with 18 women were continued for more than a year without the appearance of a single case of pellagra.

Canned salmon, a comparatively cheap, readily available preserved food, is a valuable addition to the diet in rural areas of the South in which pellagra is endemic in the spring and summer months.

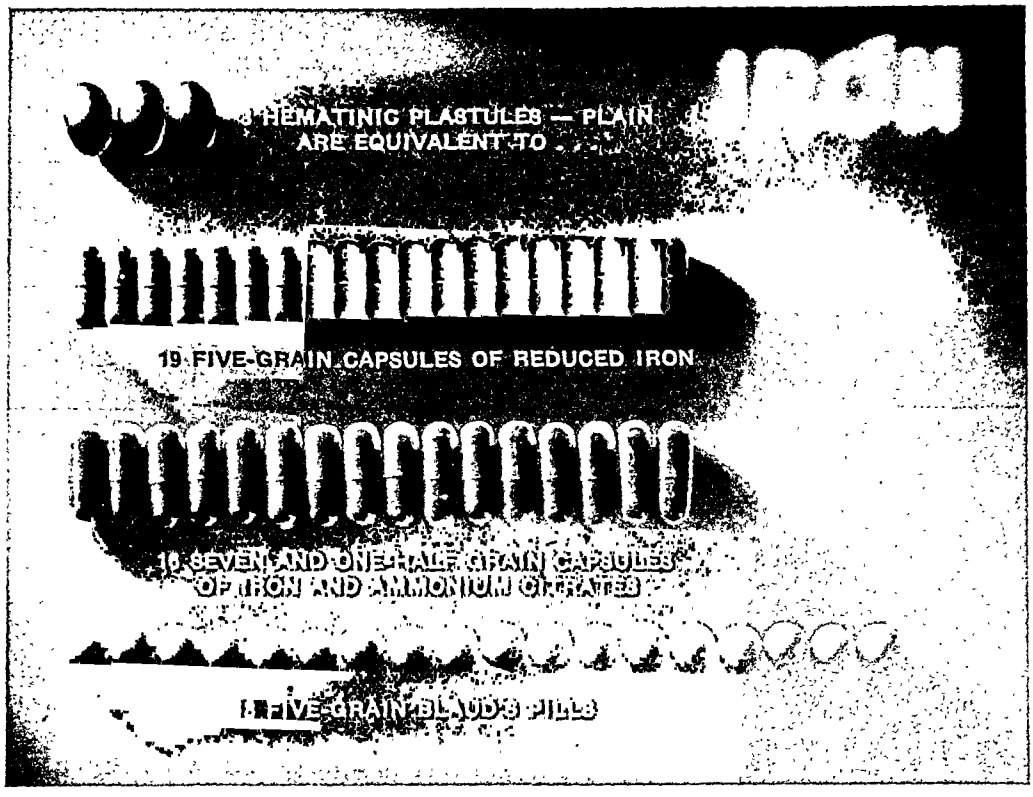
WHEELER, G. A.

The Pellagra-Preventive Value of Canned Spinach, Canned Turnip Greens, Mature Onions, and Canned Green Beans. U. S. Public Health Reports, 46, 2663, 1931.

A pellagra-producing basic diet was supplemented with 482 grams daily of commercially canned turnip greens. Not a single case of pellagra developed in 15 women fed the above diet for more than a year.

The author concluded that turnip greens might well be included in any program designed to bring about permanent control of pellagra.

MILLER, CAREY D.



Vitamin C in Fresh and Canned Pineapple. J. Home Econ., 17, 377, 1925.

The low pH of pineapple helps to prevent any marked destruction of its original vitamin C content during the relatively light process which it receives when commercially canned. Since excellent growth rates were obtained from feeding 7 grams of canned pineapple and 5 ml. of the juice, it is considered a good source of vitamin C, being only slightly inferior to the fresh product.

MACLEOD, GRACE AND BOOHER, LELA.

The Antiscorbutic Content of Some Preserved Foods. J. Home Econ., 22, 588, 1930.

The vitamin C content of canned grapefruit is about equally distributed between the pulp and the juice. The loss of vitamin C during canning is estimated at between

HEMATINIC PLASTULES

IMPROVED IRON MEDICATION

Large doses of iron are no longer necessary for the successful treatment of hypochromic anemia. Independent investigations have proved that Hematinic Plastules yield rapid clinical response, equivalent to the results obtained from massive doses of other forms of iron • The average patient requires only three Hematinic Plastules Plain daily which obviates the unpleasant effects usually associated with massive iron feedings • We will be pleased to send samples and literature on request.

10 and 15 per cent, placing the protective level somewhere between 2.2 and 2.8 grams. Rated in terms of units, canned grapefruit contains between 206 and 162 Sherman units per pound, which ranks it as one of the best sources of vitamin C.

GUERRANT, N. B., RASMUSSEN, RUSSEL A. AND DUTCHER, R. ADAMS.

The Value of the Chemical Titration Method in Determining the Vitamin C Potency of Certain Food Substances. J. Nutrition, 9, 667, 1935.

Canned sauerkraut juice was found by titration with 2,6-dichlorophenolindophenol to contain 0.082 mg. of ascorbic acid per milliliter. The calculated minimum protective dose for guinea pigs was 6.2 ml.

On the basis of these data canned sauerkraut juice may be considered a fair source of the antiscorbutic vitamin.

FELLERS, CARL R. AND ISHAM, PAUL D.

Vitamin C in Canned Citrus Products. J. Home Econ., 24, 826, 1932.

As a result of feeding tests on guinea pigs, it was found that approximately 1.2 grams of canned grapefruit slices afford protection from scurvy, which ranks it as one of the richest vitamin C foods.

One and one-half grams of canned grapefruit juice gave protection from scurvy, which also classes it as an excellent source of vitamin C.

The canned fruit used in this experiment had undergone from 6 to 9 months' storage.

WHEELER, G. A. AND HUNT, D. J.

The Pellagra-Preventive Value of Green Cabbage, Collards, Mustard Greens, and Kale. U. S. Public Health Rpts., 48, 754, 1933.

A pellagra producing basic diet was supplemented with 534 grams daily of commercially canned kale. A group of fourteen women was fed this diet for a year without the appearance of a single case of pellagra. Canned kale is a good source of the pellagra-preventive factor.

WHEELER, G. A. AND HUNT, D. J.

The Pellagra-Preventive Value of Green Cabbage, Collards, Mustard Greens, and Kale. U. S. Public Health Rpts., 48, 754, 1933.

A pellagra producing basic diet was supplemented with 482 grams of commercially canned collards daily. Thirteen women were fed this diet for a year without a single case of pellagra appearing.

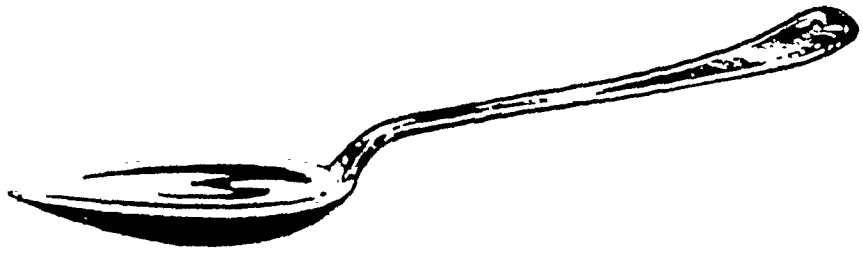
Commercially canned collards could be used for the control of pellagra in the rural sections of the South.

WHEELER, G. A. AND HUNT, D. J.

The Pellagra-Preventive Value of Green Cabbage, Collards, Mustard Greens, and Kale. U. S. Public Health Rpts., 48, 754, 1933.

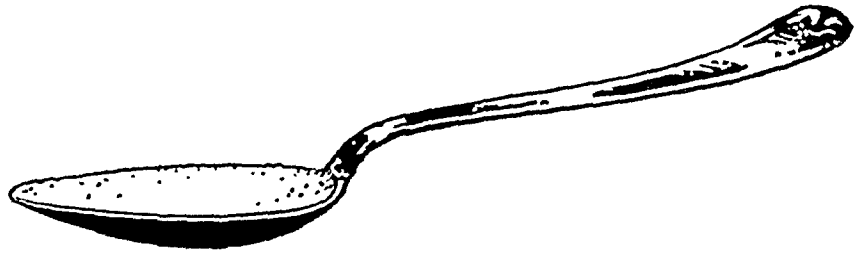
A pellagra producing basic diet was supplemented with a daily serving of 482 grams, including the can liquor, of commercially canned green cabbage. One case of pellagra developed in 16 women kept on the diet for a year. 482 grams was the border line dose of this vegetable.

Canned green cabbage is a valuable food for supplementing the diet in the rural areas of the South to control pellagra.



WHEELER, G. A. AND HUNT, D. J.

The Pellagra-Preventive Value of Green Cabbage, Collards, Mustard Greens, and Kale. U. S. Public Health Rpts., 48, 754, 1933.



A pellagra producing basic diet was supplemented with 533 grams, including the can liquor, of commercially canned mustard greens. One case of pellagra developed in 14 women kept on this diet for a year.

Canned mustard greens are a fair source of the pellagra-preventive factor and could well be included in the diet for the control of pellagra.

Synopsis of

Digestive Diseases

By JOHN L. KANTOR, Ph.D., M.D.,
Associate in Medicine, Columbia University.
260 pages, 40 illustrations. Price, $3.50.

This book presents simply, clearly and concisely, the essential facts concerning the diseases of digestion. An effort has been made to preserve the proper balance between *stress and subordination, inclusion and omission*; and to emphasize throughout the ways in which gastro-enterology fits into the larger field of internal medicine. To this end the opening chapter on classification has been designed for early orientation, clinical syndromes common to many diseases have been elaborated as fully as possible, and a final section has been devoted to digestive symptoms in extradigestive diseases.

In the preparation of this book the writer has drawn on his clinical records for much of his basic statistics, as well as on his practical experience in *teaching gastro-enterology* to both undergraduate and graduate students. The current literature, in periodicals and in special monographs, has been carefully, and it is hoped critically, utilized.

The illustrations, most of them original, and all of them drawn especially for this book, include several synoptic charts devised for the diagramatic presentation of the more important diseases. The special diet forms are derived in practically all instances from the Montefiore Hospital Manual of Diets.

Synopsis of

Ano-Rectal Diseases

By LOUIS J. HIRSCHMAN, M.D., F.A.C.S.,
Professor of Proctology, Wayne University.
288 pages, 174 illustrations. Price, $3.50. 6 color plates.

This work goes into detail especially in the technic of methods of diagnosis and details of treatment which can be administered without the use of general anesthesia. Many methods of office treatment are described and clearly illustrated. Care has been taken to present methods of treatment which do not require complicated or expensive electrical or other apparatus. It does not attempt to treat of the major diseases of the rectum or of the colon but is designedly limited to the treatment of the commoner diseases of the anus, anal canal and the rectum. The diagnosis, however, of *major conditions such as carcinoma*, are included of necessity in order to avoid pitfalls for the unwary.

This synopsis has all the salient material of the Fourth Edition of Hirschman's "Handbook on Diseases of the Anus and Rectum" condensed and brought up to date and in addition many methods of diagnosis and treatment which should assist the general practitioner of medicine in acquiring a better knowledge of those diseases of the anus and rectum which are amenable to treatment outside of the purview of the specialists.

a, recorder for circular muscle; *b*, recorder for longitudinal muscle; *c*, distention recorder; *d*, small wire crotches for pinching and holding thread; *e*, *f*, and *g*, writing lever; *h*, bar which is clamped to side of tank.

recorder one has to make a little rent in the bloodless, transparent part of the mesentery, but this does not seem to have any injurious effect. Occasionally one may have to tie the bowel in place with the help of a fine thread put through the mesentery.

The tracings made with the distention recorders usually showed oscillations due to the rhythmic contractions of the bowel. It seemed at times, also, as if the distention recorder were serving somewhat as a plethysmograph to record small changes in the volume or thickness of the wall of the bowel. All in all, I think this new recorder is the best available for the recording of rush waves in the intestine of the rabbit.

Records made simultaneously with the help of the three types of enterographs attached to one short segment of bowel. Records were made during the passage of rushes through a short segment of bowel, usually several centimeters long, to which were attached the three types of recorders. In this way I could see not only how the records differed, but also, by placing distention recorders at the oral and caudal ends of the segment, with a circular and a longitudinal recorder in between, I could tell when fluid entered and left the segment and could distinguish between relaxation and distention.

When a rush passed, all four records usually looked much the same, all the levers having risen and fallen in unison. If the circular and longitudinal recorders had shown distention by a fall in the record, as I originally expected them to do, the tracings obtained with them should have been mirror images of those obtained with the distention recorders. Actually, it was only occasionally that the circular and longitudinal apparatus recorded distention as a drop in the level of the record.

Although puzzles remain, the tracings made with the distention recorders now show happenings that correspond well with the impressions gained by the observer while he watches rushes passing through nicotinized bowel or bowel injured by anoxemia. They show occasional distention which is not followed by active contraction, but only by a slow tonic restoration of the original diameter of the bowel. They help also in distinguishing between a normal rush and an imperfect one, something which the old recorders commonly failed to do.

Unfortunately for the student of peristalsis who would like to differentiate abnormal and normal rushes, even fast rushes in apparently normal animals do not always run down the bowel evenly as one might expect them to do. Occasionally the records will show that a particular segment was suddenly distended with fluid or gas and thus stimulated to contract at a time when the crest of the oncoming wave was still 50 cm. orad. At other times it will be seen that a segment contracted ahead of time in spite of the fact that no fluid had yet entered it. Not infrequently, also, the person who watches a big wave will get the impression that it consists of a series of disconnected short rushes, and yet the records of distention will show that each time, as a contraction died out, some of the moving column of fluid seeped on and apparently gave rise to a rush further caudad. In other cases the recorders show that a definite shallow ripple passed from one active segment to another, invisible to the unaided eye.

With the distention recorder a good quick rush in a normal bowel commonly produces in the tracing a sharp peak. When the neuromuscular mechanism of the bowel has been injured by anoxemia or nicotine, there may still be a sudden distention, with a sharp rise of the point of the lever, but then it drops slowly during a period of a minute or more. During this

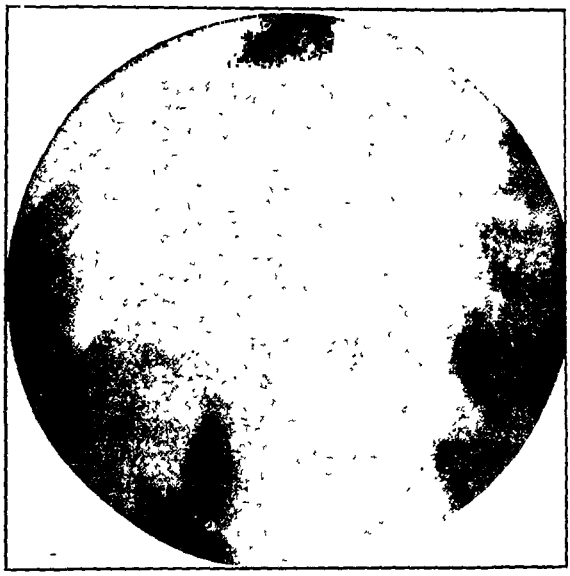

Fig. 1. Showing typical pancreatic stones.

40 to 45 units of insulin a day were required to control glycosuria.

On the first physical examination there were no significant findings other than moderate emaciation. Marked glycosuria, with a fasting value for blood sugar of 163 mg. per 100 c.c., was noted. Roentgenologic examinations of the gastro-intestinal tract and gall bladder were negative; those of the small bowel did not reveal any demonstrable abnormality. A test of liver function with bromsulphalein showed no retention of dye, the rate of hippuric acid conjugation was normal, the serum bilirubin was normal in amount and reaction, and there was no reduction in serum protein (7.24 gm. per cent). The serum lipase, which is usually elevated in acute pancreatitis, was within normal limits. Complete absence of pancreatic secretion was demonstrated by studies on the duodenal content. Roentgenograms of the upper part of the abdomen disclosed numerous small calcified areas which seemed to be distributed throughout the body of the pancreas (Fig. 1). There was some question as to the benefits which might be derived from operation, but it was nevertheless felt that exploration was justified in the hope that the pancreatic duct could be freed of stones. At operation a mass of adhesions was found in the right upper portion of the abdomen; the gall bladder was slightly distended, the common duct was about twice the normal size, and the liver was apparently normal. The pancreas was much firmer than normal and was enlarged to about three times the normal size. Since it seemed that the stones could not be removed from the pancreatic ducts without grave risk, only cholecystostomy and choledochostomy were performed in the hope of relieving the pancreatic infection presumed to be associated with the condition.

Following operation the patient got along well for about three months when marked diarrhea appeared, as it had at various times in the past. He had as many as twelve stools in twenty-four hours; they were of an offensive odor, and were bulky and fatty. Since this steatorrhea was obviously due to deficiency of external pancreatic secretion and it did not respond to symptomatic measures, pancreatic juice obtained from dogs according to the method of Bargen, Bollman and Kepler was administered by duodenal tube and in a dried form. The details of this study are reported elsewhere; suffice it to say here that there was prompt and definite improvement in the patient's condition, the number of stools decreasing to two in twenty-four hours. He was allowed to return home and got along fairly well until the summer of 1936 when he again experienced attacks of abdominal pain similar to those described earlier. Following such episodes of pain, glycosuria and diarrhea increased, and following the last attack, in September, 1936, slight jaundice and marked ascites and edema made their appearance.

On physical examination at the clinic at this time enlargement of the liver was noted, its edge being palpable 8 cm. below the costal margin. The spleen was definitely enlarged, and a few distended veins were visible over the abdominal wall. The stools contained only a moderate amount of fat and the diabetes was about of the same severity as before, requiring 40 units of insulin daily for control. The fasting value for blood sugar was 200 mg. per 100 c.c. On two examinations the duodenal juices were found to contain no pancreatic ferments whatever. Blood smears revealed macrocytosis typical of disease of the liver. The bromsulphalein test of liver function revealed retention of dye grade 3; the hippuric acid test showed some reduction in liver function (2.26 gm. calculated as benzoic acid). The value for blood cholesterol was 192 mg. and for cholesterol esters 136 mg. per 100 c.c.; serum proteins were 7.3 gm. and serum bilirubin 2.9 mg. per 100 c.c., the van den Bergh reaction being direct.

In discussing the physiologic aspects of this case with Dr. Bollman, who had prepared the pancreatic juice used in the treatment of the patient's steatorrhea, the possibility of fatty change in the liver due to the primary pancreatic lesion was first considered. While attempting to obtain a supply of lipocaic for treatment, it was decided to attempt to control the ascites and edema by increasing the intake of carbohydrate, by giving ammonium nitrate in full doses and by intravenous injections of salyrgan. On this regimen distention of the abdomen decreased rapidly and the peripheral edema disappeared. Through the courtesy of Dr. Dragstedt, sufficient lipocaic for twelve days' use was supplied. During that period the liver definitely decreased in size, and dye retention which had previously been graded 3 was reduced to grade 1. Later protamine insulin was substituted for ordinary insulin, about 80 units being given on alternate days. At the time of dismissal the diet consisted of 250 gm. of carbohydrate, 60 gm. of protein, and 122 gm. of fat (2,340 calories). The patient was considerably improved generally; there was no ascites or edema and the fatty diarrhea was under satisfactory control.

On March 1, 1937, the patient wrote that he was feeling remarkably well, that there had been no return of the ascites or edema, and that the diarrhea had not recurred. The administration of lipocaic will be continued for an indefinite period.

In this case there is good evidence to show that the primary pancreatic lesion was of long duration and that whatever lesion developed in the liver was of much more recent date and of rapid development. Hepatic functional tests and careful inspection of the liver at operation, early in 1935, did not reveal any significant changes; the hepatic and splenic enlargement, the ascites and edema, and other evidences of hepatic involvement appear to have developed acutely a year later. It is possible, but by no means certain, that the immoderate use of alcohol hastened the process. The prompt improvement under treatment, the decrease in the size of the liver and reduction in dye retention when lipocaic was given, and the marked and rapid general improvement in the patient's condition argue for a diffuse fatty change rather than for the presence of the ordinary forms of portal cirrhosis.

In Case 2, the available information is less conclusive, but the clinical picture is very suggestive of a more or less identical change in the liver. Here again

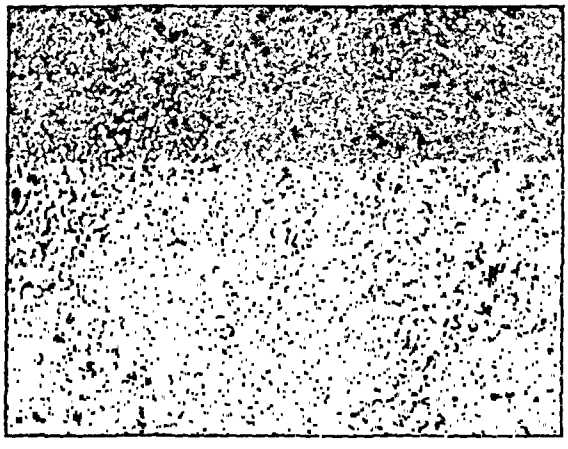

Fig. 2. Fatty infiltration of the liver of a patient with extreme pancreatic atrophy (x100).

there is little to suggest the possibility of a permanent type of structural hepatic damage, although the pancreatic lesion was undoubtedly of long duration:

Case 2. The patient, a physician, aged forty years, came to the clinic in January, 1936, complaining of intermittent jaundice and abdominal cramps. There was a history of alcoholism, and many of his digestive complaints were more or less intimately associated with drinking bouts. On reviewing the history, the patient described attacks of upper abdominal pain which were projected to the left and were accompanied by nausea, chills, vomiting and fever. Jaundice and diarrhea had accompanied or followed these attacks. During the two years preceding registration at the clinic, the patient had lost 50 pounds (22.7 kg.) and had become extremely nervous and weak. Shortly before coming to the clinic ascites and edema had developed.

On physical examination the patient was found to be weak, pale, and slightly jaundiced. The abdomen was distended with fluid and a number of large superficial veins were observed over the anterior abdominal wall. The edge of the liver was felt about 4 cm. below the costal margin; the spleen was also moderately enlarged. Because of the patient's poor condition, he was hospitalized and a tentative diagnosis of portal cirrhosis and ascites was made. Urinalysis was essentially negative; the value for hemoglobin was 13.3 per 100 c.c., and erythrocytes numbered 4,200,000 and leukocytes 7,100 per cubic millimeter of blood. The differential count was essentially normal, but morphologic examination of the blood smears revealed a "toxic" blood picture with definite macrocytosis. The plasma coagulation index and number of platelets were normal, 1.3 and 170,000, respectively. Blood urea, blood sugar, and plasma chlorides were, respectively, 16, 95, and 608 mg. per 100 c.c. The serum protein was 5.63 gm. per 100 c.c. and the albumin-globulin ratio 1.08:1. The blood cholesterol and cholesterol esters were, respectively, 89 and 60 mg., and the blood calcium was 8.8, phosphorus 3.2 and phosphatase 7.2 mg. per 100 c.c. Two tests for serum lipase gave results of 0.7 and 0.35 c.c., respectively, as measured in cubic centimeters of tenth normal sodium hydroxide. The Takata-Ara test was strongly positive. A liver function test with bromsulphalein showed dye retention, grade 1. The serum bilirubin reading was 1.4 mg. and gave a direct reaction. The benzoic acid excretion was 3.22 gm. in four hours. Roentgenologic examinations of the thorax, stomach, small intestine, colon and terminal portion of ileum were negative. A cholecystogram showed a nonfunctioning gall bladder and multiple pancreatic calculi. Stool tests showed oil and fat in excess and contained bile in good quantities, the total fat in one specimen measuring 16.3 per cent. Duodenal drainage revealed bile in normal quantities, but there was no amylase or trypsin present.

A diagnosis was made of chronic pancreatitis with lithiasis, pancreatic insufficiency with absence of external pancreatic ferments, and secondary hepatic change, presumably due to fatty degeneration. Treatment with a high carbohydrate diet, glucose intravenously, and small doses of salyrgan, produced a remarkable diuresis and relief from ascites and edema. Some general clinical improvement was noted while the patient remained in the hospital and subsequent correspondence indicated that he had done fairly well except for attacks of abdominal pain.

In comparing the course of this patient with that in Case 1 it seems quite likely that this patient's principal complaints were due to primary pancreatic lithiasis with secondary fatty changes in the liver, the latter factor being, no doubt, affected by the use of alcohol. The laboratory evidence of rather moderate parenchymatous hepatic damage and the ease with which ascites and edema cleared under treatment suggests again a fatty type of liver rather than one which was the site of nodular cirrhosis. In a third case, in which the findings will not be presented in detail, pancreatic lithiasis, steatorrhea, and diabetes mellitus have been demonstrated; the evidence of hepatic damage rests upon a single positive bromsulphalein test, a moderately elevated icterus index, and a slightly enlarged liver; it will be interesting to see if more definite signs of hepatic insufficiency will ensue at a later date.

COMMENT

In the cases just described, hepatic insufficiency of various degrees appeared as a probable sequel of pancreatic lithiasis and pancreatic insufficiency. On reviewing the literature it was found that in a few cases of pancreatic stone or atrophy the liver had been described as affected in various ways. Most authors describing cases of chronic pancreatic atrophy or lithiasis, however, do not mention hepatic changes, the reasons being that complete pancreatic insufficiency due to stone is of relatively uncommon occurrence and that extensive destruction of pancreatic tissue is probably required to produce any fatty deposits in the liver. Fiessinger and Olivier (1933), however, comment on the association of hepatic disease in cases of pancreatic lithiasis and reported a case with proved cirrhosis. Vallery-Radot and his colleagues described another case in which pancreatic stones were associated with cirrhosis and primary malignancy of the liver. Choy and Oh have described the case of a young woman whose pancreas was affected by lithiasis; at necropsy the liver weighed 1,560 gm. and was very fatty. Paviot and his associates (1935) reported an almost identical case, the liver weighing 2,050 gm. and showing extreme fatty degeneration. In a recent case reported by Thompson, McQuarrie and Bell there was hypoproteinemia, ascites, and edema; at necropsy a very fatty and somewhat atrophic liver was found, but there was no description of any lesion in the pancreas which might explain it. Binger and Keith's case of ascites and edema of indeterminate origin, with complete atrophy of the pancreas and a fatty liver, was strikingly similar to the last two mentioned. Because of its intimate bearing on the subject and the completeness of their study, we have obtained their permission to present it in some detail:

The patient, a man aged sixty-two years, came to the clinic in February, 1934, complaining of edema and ascites which had been present for about five months. There was an antecedent history of fatty diarrhea extending over a period of about five years; numerous and varied diets and medications had failed to relieve the condition.

On physical examination the patient was found to be pale and weak. There was a small amount of fluid at both lung bases and the abdomen was distended with fluid, but neither the spleen nor liver could be made out. Peripheral and general edema was also noted. Urinalyses were negative, with albumin appearing only in traces; renal functional studies revealed mild renal insufficiency. The serum protein was 3.6 gm. per 100 c.c. and the albumin-globulin ratio was 1:1.6. The blood cholesterol was low (75 mg. per 100 c.c.). A liver function test with bromsulphalein showed dye retention, grade 3, and a later one retention of grade 2. Blood studies were interesting, revealing definite marked anemia; the value for hemoglobin was 11.5 gm. per 100 c.c.; erythrocytes numbered 3,750,000, and leukocytes 9,600 per cubic millimeter. Examination of the smears was not diagnostic, but active erythrocyte regeneration was noted. Gastric analysis showed an absence of free hydrochloric acid. Successive stool tests showed an excess of fat or oil but were otherwise negative. The patient was given a high protein diet, together with raw liver, Adex tablets and calcium lactate. Potassium nitrate and salyrgan produced satisfactory diuresis, with a loss of 37 pounds (16.8 kg.) of edema fluid.

No definite diagnosis was established, and the condition was classified as one of the indeterminate edemas associated with hypoproteinemia. The question of pancreatic disease was raised, but there was no proof to support such a diagnosis other than the fatty stools. It was agreed that the patient had a hepatic lesion of some type, but its nature was uncertain. He returned to his home where he gradually failed and died on April 7, 1934.

A complete postmortem examination revealed multiple cysts of the pancreas, with extreme atrophy of the pancreatic tissue, bilateral hydrothorax, hydropericardium and ascites. Microscopic section of the pancreas revealed only a few ducts, moderately dilated, practically no acinar tissue, and no islands of Langerhans. Between the ducts there was a large amount of dense connective tissue. No evidence of fat necrosis and no signs of any specific inflammatory phenomenon could be demonstrated. There was sufficient anatomic basis to conclude that there was practically total pancreatic insufficiency, certainly of the acinar tissue, and possibly also of the islands.

The liver showed extensive fatty changes in the cells and terminal congestion of the sinuses, but there was no other fundamental pathologic change except for extreme fatty infiltration (Fig. 2). There was no increase in connective tissue or suggestion of cirrhosis. No renal pathologic change was observed grossly or microscopically.

There was some question as to whether or not the fatty change in the liver was sufficient to account for the ascites, edema, and hypoproteinemia, but in view of the cases previously described and the work which has been reported on pancreatectomized animals, it seems reasonable to suppose that fatty degeneration of the liver secondary to pancreatic atrophy existed.

A search of the records of the Department of Pathology at the clinic reveals nine cases of pancreatic lithiasis, the essential details of which have been described by J. G. Mayo. In three cases there was some degree of fatty change; the remainder showed no striking change in the liver except in one case with hemochromatosis where cirrhosis was a feature. In only one of the remaining cases was destruction of pancreatic tissue complete; one must therefore assume in the others that sufficient pancreatic tissue was present to maintain normal fat metabolism. Quite probably a further search of clinical and postmortem material will reveal other cases in which pancreatic disease is followed by parenchymatous hepatic lesions of a fatty type.

SUMMARY AND CONCLUSIONS

Experimental and clinical evidence is cited which seems to demonstrate: (1) the occurrence of fatty degeneration of the liver when there is extensive destruction of the pancreas, (2) that the absence of the hormonal substance, lipocaic, may be the inciting factor for these changes in the liver, and (3) that there may be some therapeutic use for this preparation in certain clinical cases of pancreatic disease. If this is not available, the feeding of raw pancreas and diets high in lecithin is suggested. The possible relation of fatty change to the later development of cirrhosis invites speculation.

Hydrogen Peroxide as a Depressant of Gastric Acidity*

By

and

A. C. IVY, Ph.D., M.D.

CHICAGO, ILLINOIS

A GREAT amount of work has been done in search of methods for decreasing the acidity of the gastric contents. One of the substances which has been used for this purpose is hydrogen peroxide. Petri (1) in 1908 reported that large quantities of a dilute solution (300 c.c. of a 0.5% solution) introduced into an empty stomach markedly lowered the acidity of the gastric contents and recommended its use in the treatment of hyperacidity. Since then a number of clinicians (2, 3, 4, 5, 6 and 7) have reported that dilute hydrogen peroxide is a means of reducing the secretion of gastric acid and of increasing the secretion of mucus. All agreed that acid secretion was reduced, but not all recommended its therapeutic use. The degree of inhibition of acid reported varied. Hurst (8) in 1931 reported the use of hydrogen peroxide for relieving the achlorhydria or hypochlorhydria seen in chronic gastritis. He used solutions varying from 0.013% to 0.095% as a gastric lavage. It is to be noted that Hurst used hydrogen peroxide in much more dilute solutions than did the others. He supposed that it was an effective mechanical means of dislodging the excessive mucus which was present in chronic gastritis. He suggested that excessive mucus prevented acid secretion by blocking the mouths of the acid-secreting glands.

For some time one of us (A.J.A.) has been interested in studying experimentally the effects on gastric secretion of various agents when applied to the gastric mucosa of animals. Our review of the literature indicated that the effect of hydrogen peroxide on gastric secretion should be studied under controlled laboratory conditions. This we have done; in addition we have extended our studies to include a few human subjects.

METHODS

Five Pavlov pouch dogs and three dogs with intact stomachs were used. All were in good health at the time the experiments were initiated. Five clinic patients were studied; the clinical diagnosis was duodenal ulcer in three, and gastric ulcer in one; one had a normal stomach insofar as could be determined by physical findings and laboratory tests, but he complained of dyspepsia and epigastric distress.

The secretion of the pouch dogs was collected by the orthodox method. In the dogs with intact stomachs the gastric contents were aspirated by means of a number 32 French colon tube which was passed each time a sample was to be withdrawn. We first tried using a retained Rehfuss tube; it worked well during the control tests, but after hydrogen peroxide had been administered there was so much mucus on subsequent aspirations that the small tube invariably became occluded. In the human subjects a Rehfuss tube was used.

Two methods of stimulating the gastric secretion were used. Histamine was used in all three groups of subjects; in each case 1.0 mgm. of ergamine acid phosphate was injected subcutaneously. In addition, on the dogs with pouches, tests were made in which the stimulus was a test meal.

In the dogs with pouches when histamine was used as the stimulus, a control test started with the injection of the histamine, the gastric samples being collected several times during a period of 90 minutes. At the end of 90 minutes another milligram of histamine was injected and the collection of juice continued. In the dogs with intact stomachs and the human subjects, only one test period of 90 minutes was employed. In the case of the dogs with pouches when a meal was used as a stimulus, the secretion was collected for a period of eight hours after feeding.

In the case of each subject a number of control tests were made to establish the normal response of the individual to the stimulus being used.

RESULTS

The complete data are too bulky to be presented. Therefore we shall give a representative protocol of one of the experiments and will then summarize the results obtained in the remainder.

The effect of a single application of 3.0% hydrogen peroxide on the histamine response: Dog No. 1 had a Pavlov pouch. On injecting 1.0 mgm. of histamine the pouch secreted an average of 14.0 c.c. of gastric juice containing 53 mgm. of free HCl and 63 mgm. of total acid in 90 minutes. After the necessary control tests, the pouch was washed with 100 c.c. of 3.0% hydrogen peroxide (see Table I). Beginning 15 minutes later the secretion of the pouch was collected for two 30 minute periods. During this time the secretion was mucoid in nature, amounted to 18.2 c.c., and contained no free acid, but had a slight amount of total acid. Then 1.0 mgm. of histamine was injected subcutaneously. In 90 minutes 23.2 c.c. of secretion were collected containing only 6.00 mgm. of free HCl and 21.60 mgm. of total acid. Then the injection of histamine and collection of secretion were repeated with the results shown in Table I. The results of all these particular experiments on Dog No. 1 are included in Table II. The results show clearly that washing the pouch with 3.0% hydrogen peroxide markedly depressed the secretory response to histamine. The juice was rich in mucoid secretion.

In the five dogs in which this experiment was performed, the free HCl secretion was reduced on the average 65.8% after the first injection of histamine and 56.5% after the second. The volume of mucoid secretion obtained varied widely, but was increased in all.

Following a single treatment of the pouch with

Submitted January 23, 1937.

hydrogen peroxide, the dogs were injected daily with histamine to determine the time at which the secretory response returned to normal. The time of recovery varied widely. One dog had not returned to normal in 29 days. One returned to normal in 5 days, one in 9 days, one in 10 days, and one in 12 days. One secreted hypernormally at 12 days, one at 15 days, and another at 18 days.

The effect of repeated applications of 3.0% hydrogen peroxide on the histamine response: In two of the dogs whose response to histamine had returned to normal in from five to nine days after a single application of hydrogen peroxide, 3.0% hydrogen peroxide was applied to the pouch twice daily, morning and evening, for 15 days. The response to histamine was determined on the third, fifth, eighth, eleventh, and fifteenth days. The secretion of free and total acid was reduced markedly in both dogs. In one dog the free acid was reduced by 96% (almost abolished), the total acid being reduced 83%. In the other the free acid was reduced 77% and the total acid 46%. The volume of secretion, chiefly mucoid, was reduced 23% in one and increased 48% in the other. From the first dog, on some days, a clear rather dilute mucoid secretion devoid of free acid (pH 4.2) was obtained.

The effect of a single application of various concentrations of hydrogen peroxide on the histamine response was studied in the three other dogs with pouches. It was found that a 0.5% solution was effective in reducing the secretion of acid, the average varying from 12% to 66% in the total acid and from 32% to 83% in free acid in the different dogs. The results, as might be anticipated, showed that the stronger the concentration the greater the reduction in acid secretion. Concentrations of 0.5, 1.0, 1.5, 2.0, and 3.0% were employed.

The results with a meal as the stimulus: After the pouches had returned to normal and suitable response to the test meal had been obtained, the hydrogen peroxide was applied and the meal fed. The secretion of the pouch after the meal was collected for eight hours.

The data are shown in Table III. The results are exceedingly variable, much more so than the results obtained with histamine as a stimulus. This should be expected because the response to the stimulus of a meal is normally more variable than the response to histamine. The variation may be about 25% from day to day in the same dog. Further, after the first hour or two following the application of the peroxide and feeding, acid secretion starts to increase. The amount of secretion varies in the same and different dogs. It must be recalled that the histamine response occurs only during a period of from one to one and one-half hours. It is to be noted that a 3% solution was required to produce a definite reduction of the free acid in two of the three animals in series 2; and in series 1, dog No. 2 showed little decrease even to 3.0%.

In one dog (No. 8) a 2% solution was effective. Dog No. 11 manifested a definite increase in acid secretion after the application of each of the concentrations of peroxide except the 3% solution. This is the animal that showed the most marked hypernormal response to histamine during the recovery of the pouch from the effect of 3% peroxide.

Dogs with normal stomachs. Three dogs with intact stomachs were treated with 100 c.c. of 3% hydrogen peroxide after several control responses to histamine had been obtained. The peroxide solution was withdrawn after three minutes. The secretion of free acid was reduced from 95% to 100%, and the total acid was reduced from 81% to 90%. The secretion of mucus was so copious that a colon tube had to be used to aspirate the gastric contents. The dogs were nauseated and retched after the aspiration of the peroxide. One of the dogs on being treated again on the following day showed a large amount of blood in the gastric contents.

This depression of secretion was anticipated. The greater viscidity of the secretion probably was due to stimulation of the mucosa of the pyloric antrum in addition to that of the fundus. Nausea and vomiting did not occur in the dogs with Pavlov pouches for several reasons. The area to which the peroxide was applied was smaller. The nauseating effects of the stomach tube were absent. In the animals with whole stomachs some of the hydrogen peroxide undoubtedly passed into the duodenum. Three per cent peroxide obviously was too irritating for the stomach of one of the animals.

HUMAN SUBJECTS

Because 3.0% hydrogen peroxide was found to be markedly irritating to humans, 1.0% and 2.0% solutions usually were employed. A 3.0% solution was used in the "normal" individual in a few tests. Histamine was used as a stimulus. The entire content of the stomach was removed every ten minutes for 90 minutes after the injection of histamine. From three to five control responses to histamine were obtained prior to the commencement of treatments with hydrogen peroxide. The stomach was lavaged with from 100 to 300 c.c. of the peroxide which was withdrawn after three to five minutes. This procedure was repeated two or three times a week, until four to twenty treatments had been given.

In one patient with duodenal ulcer in which only 1.0% peroxide was used, the acid secretion after five treatments was increased by about 35% in spite of the

acid by 18%; this patient secreted much mucus. Because the symptoms were not decreased, the treatment was discontinued. The stomach of the third patient with duodenal ulcer was lavaged eight times with 1.0% and 2.0% solution of peroxide. Five tests were performed during a three week period. Discomfort from the lavage occasionally was reported. The two per cent solution of peroxide decreased the free acid values by about 90% and the total acid values by about 30%. The symptoms of this patient disappeared with this regime without other medication or dietary changes. In the patient with a gastric ulcer, 1.0% solution of peroxide increased the secretion of both acid and mucus; 2.0% caused a decrease of about 50% in the acid values. The treatment was discontinued because the patient's symptoms were not relieved after nine treatments during a period of four weeks, and because there so frequently was considerable blood in the gastric contents following hydrogen peroxide. In the individual with a "normal" stomach, concentrations of peroxide varying from 1.0% to 3.0% were used. Twenty treatments were given and nine tests were done during this time. More patients were not used because of the discomfort and bleeding experienced by those we did treat in this way.

The results of the tests confirmed the observations on the dogs, that 3.0% solution of peroxide reduced acid values in response to histamine to a greater extent than the 1.0% solution. In the patient with gastric ulcer and in one of three patients with duodenal ulcer a 1.0% solution of hydrogen peroxide increased the acid values of the stomach contents after histamine. In the other two patients with duodenal ulcer either 1.0% or 2.0% solution of hydrogen peroxide reduced the acid values after histamine. In the individual with a "normal" stomach 1.0% to 3.0% solution of hydrogen peroxide lowered the acid values in response to histamine, the stronger solution being the more effective.

DISCUSSION OF RESULTS

The preceding results indicate that in general the lavaging of the stomach with hydrogen peroxide solution (½-3%) produced a decrease in the acid of the gastric contents when either a meal or subcutaneous injection of histamine was used to stimulate acid secretion. This decrease was observed in the per cent of acid in the gastric contents and in the total milligrams of acid, both free and total, in each case. The stronger the solution of hydrogen peroxide used the greater was the decrease of acid response. This decrease varied widely in different subjects, and also, from time to time, in the same subject. However, one of the dogs and two of the five human subjects consistently showed increases in acid secretion rather than decreases. The mucous secretion always was augmented.

At times there was a complete absence of free acid (but no instances of complete absence of total acid) in response to histamine stimulus. This was observed four times in dog No. 1, once in dog No. 2, twice in dog No. 8, twice in dog No. 6, twice in dog No. 9, and twice in dog No. 12. However, it was the exception rather than the rule. This type of secretion was observed by Ivy (9) and Dawson (10) in the gastritis produced in Pavlov pouch dogs by X-rays.

While no chemical analyses for content of mucus were made, it was obvious that generally an increase in mucoid or mucus secretion paralleled a decrease in acidity. This observation certainly was true in those tests in which no free acid was found. In several instances when there was no free acid, determinations of the chloride in the secretion were made; and it was found that the chloride content was no higher than that which is normal for mucus or mucoid secretion.

Other investigators have reported using 300 c.c. of a 0.5% solution for gastric lavage of peptic ulcer patients. Petri, Poly, Hall, Kelling, and Dienst were enthusiastic in regard to the use of hydrogen peroxide in the treatment of peptic ulcer because the secretion of acid is reduced and that of mucus is increased. Hall stated, however, that it did not seem to benefit cases with active ulcer. Winternitz found that it decreased acidity for only short intervals, and discarded its use. Nielson also observed a depression of free acid with a return to normal values or nearly normal values in 24 hours. Hurst used dilute solutions (0.013-0.095%) in chronic gastritis, observing an increase in acid secretion.

Our results show that to obtain a significant reduc-

tion in acid secretion in response to histamine or a meal, stronger concentrations of peroxide (one and two per cent) must be employed. Even then stimulation, as observed by Hurst with very weak solutions, may occasionally occur. A three per cent solution is too irritating. When the weaker solutions are used the return of the secretory response to normal is relatively rapid. In the case of a "susceptible" stomach, however, a 0.5% solution applied every other day will reduce acid secretion significantly. However, we suspect that it might cause active ulcers to bleed; for the gastric ulcer patient showed bleeding with one and two per cent solutions, and one of the dogs with "normal" stomach showed marked bleeding after 3%. Although it would be desirable to have some simple and innocuous method for reducing the secretion of acid by the stomach, we do not feel that the use of hydrogen peroxide can be recommended without considerable reservation.

CONCLUSIONS

1. Hydrogen peroxide in solutions varying from one-half to three per cent when used as a gastric lavage may depress the acidity of the gastric contents. This may be true even when using histamine as the gastric secretory stimulus. However, in an occasional dog and human subject a one or two per cent solution may induce a stimulating effect. The individual susceptibility varies widely, a three per cent solution being required to depress significantly acid secretion to histamine in some individuals.

2. The stronger the solution of peroxide used, the greater is its effect in depressing the acidity.

3. Hydrogen peroxide influences the volume of gastric secretion in response to a stimulus. The volume of secretion may be either increased or decreased. The volume changes do not correlate with the changes in acidity.

4. Hydrogen peroxide stimulates the secretion of mucus by the stomach.

5. The effects of hydrogen peroxide on gastric secretion are most marked immediately after lavage. Recovery occurs in from 24 hours to 15 days, depending on the individual susceptibility and the concentration of peroxide used.

6. Hydrogen peroxide is not a satisfactory means of depressing gastric acidity in patients. It may be active in inducing hemorrhage from an ulcer. When used in the most effective concentrations it causes too much discomfort, and its effect in concentrations which do not cause discomfort cannot be predicted.

A Contribution to the Etiology of Gall Stones*

III. A study of the hydrogen-ion concentration of gall bladder bile and its effect upon gall stones

By

MAURICE FELDMAN, M.D., SAMUEL MORRISON, M.D.,
C. JELEFF CARR, M.S.
and
JOHN C. KRANTZ, Jr., Ph.D.†
BALTIMORE, MARYLAND

IT has been definitely established that the hydrogen-ion concentration of gall bladder bile varies in different animals. In the herbivorous animals the bile is normally alkaline (1), while in the carnivorous animals the bile is more likely to be acid (2). On the other hand, in the human subject an omnivorous species, the hydrogen-ion concentration is close to the neutral point (3).

The fact has been well established that human gall stones will readily dissolve in dog's bile, the reaction of which is acid, the pH. averaging about 6.1 (1). We have observed that human gall stones do not dissolve in the guinea pig's gall bladder bile, which is normally definitely alkaline (4).

Submitted March 17, 1927.

In the present investigation, an attempt has been made to render alkaline, the normally acidic dog's gall bladder bile. This was accomplished by the following method. The gall bladder was exposed and brought out to the surface and sutured to the peritoneum and skin. After the wound healed, a fistulous gall bladder was produced by opening the exposed vesicle and allowing it to drain freely. The purpose of this procedure was to prevent concentration of the bile in the gall bladder and yet maintain bile in the vesicle. In order to accomplish the latter objective the fistulous opening was allowed to heal almost completely, but still to permit a small amount of drainage. Inasmuch as these fistulas tended to heal completely in most instances, it was necessary to keep them open by frequent probing.

TABLE I

The hydrogen-ion concentration of bile in the fistulous dog

It is interesting to point out that these fistulous gall bladders presented also histopathological abnormalties. The mucosae were preserved, but distinct thickening of the gall bladder wall with lymphocytic infiltration was noted, indicating evidence of a chronic inflammatory process. Table I presents the hydrogen-ion concentrations of gall bladder bile made at varying intervals from the fistulous gall bladders. It is interesting to note from these experiments that the gall bladder bile is persistently alkaline if the fistulous opening is patent and the drainage is free, but since the opening has a tendency to close the bile tends to return to acid. The color of the fistulous bile is light yellow having the appearance of liver bile, while the normal gall bladder bile of the dog is dark green.

The premise upon which the present investigation is based is that human gall stones do not tend to dissolve in alkaline bile. This has been clearly demonstrated in the guinea pig and reported in a previous communication (4).

In nine dogs with satisfactory fistulae made in the manner already described, in which the acid bile of the dog becomes alkaline, (see Table I) further studies were made as to its effect upon stones. In order to demonstrate the effect upon the weight of the stone, it was noted that loss of weight diminishes as the proportional degree of hydrogen-ion concentration of the gall bladder bile increases, i.e. the greater the alkalinity of the bile the less effect it has on the dissolution of stones. A human gall stone was inserted in each of five dogs' gall bladders through the fistulous opening. Table II presents the hydrogen-ion concentrations of the gall bladder bile. The table clearly demonstrates the effect of alkaline bile upon human gall stones in relation to the pH. values of the bile. It would seem

that the alkalinity of bile seems to favor the formation of stones as deduced from the fact that alkaline bile does not dissolve stones and often favors an increase in its weight. This is quite in contrast to the effect of normal dog's bile upon human gall stones which has been shown to lose on the average of about 70 per cent or more of its original weight (1).

CONCLUSIONS

Our experimental investigations indicate that the change in the hydrogen-ion concentration of gall bladder bile is an important factor in the etiology of gall stones.

Peristalic Rush Studied with New Apparatus*

By

WALTER C. ALVAREZ, M.D.†
ROCHESTER, MINNESOTA

AS everyone knows, food and its residues are moved down the bowel at intervals with the help of peristalitic rushes. In the rabbit, these rushes commonly start in the duodenum about the time that a large gastric wave reaches the pylorus. They can be started by causing the animal to swallow fluids, and after going some distance they are likely to fade out or to be stopped, perhaps by an increase in the tonus and activity of the bowel out ahead. A rush in the upper part of the bowel is commonly associated with rushes farther caudad in the ileum or colon, rushes that seem to be started by a stimulus which shoots rapidly from one end of the digestive tract to the other. It is this stimulus which produces the changes in tonus and activity already referred to as appearing in segments far out ahead of the traveling disturbance (1, 2).

Mahoney and I showed that there are two important parts to a rush; one, a wave of contraction traveling in the wall of the gut, and the other, a column of fluid being pushed ahead through the lumen. This column of fluid can be compared to a long train of cars with an engine behind. If one ties a piece of tape gently about the bowel, the column of fluid is stopped and the wave in the wall goes on to pick up a new column beyond the obstruction, but if one cuts the bowel across and connects the ends with a piece of glass tubing, the wave in the wall is stopped while the column goes on to pick up a new wave in the muscle beyond the tube.

METHODS OF STARTING PERISTALTIC RUSHES

Several years ago I began to start peristaltic rushes in rabbits with the help of a measured and uniform stimulus. To obtain this, I squirted into the proximal part of the duodenum 10 c.c. of Locke's solution, under a pressure of 100 mm. of mercury. With the animal anesthetized and pithed in the way described elsewhere (3), a cut was made in the side of the bowel, and the lower end of a specially made burette (designed by Dr. Joseph Berkson) was tied in. This burette, about 30 cm. long, has two side-tubes and a cock at each end. The lower side-tube is connected with a flask containing Locke's solution, and the upper, with a flask containing air. The first flask and its contained fluid are warmed by immersion in the large tank of Locke's solution in which the animal is lying.

In order to fill the burette, one opens the cock in the lower side-tube and the one at the upper end and pumps air into the upper part of the fluid-containing flask with the help of a rubber bulb. As the salt solution is forced up into the burette, it raises a light bakelite piston which fits loosely in the lumen. The two open cocks are then closed, the cock on the upper side-tube is opened, and air is pumped in above the piston until a manometer in the circuit shows a pressure of 100 mm. of mercury. When the experimenter wishes to produce a rush he opens the cock at the bottom of the burette and the fluid squirts into the bowel. The expanding air above is kept from entering the bowel by the piston, which comes down against a ring of small knobs on the inner surface of the lower end of the burette, and is stopped there.

The moment of stimulation is recorded on the drum by means of a writing lever connected by a thread to the evacuating cock. The burette is held in place by a stand which must not touch the tank holding the animal. In order to avoid artefacts in the records care must be taken not to jar the bowel, the animal, or the tank just before a rush is started.

Still further to avoid doubt on this point, I fastened each of the six recorders used in an experiment to one end of a short segment of soldering wire which was then set in a hole in a bar clamped to the side of the tank, as in Figure 1, *h*. The use of such easily bent soldering wire is a great help because with it the experimenter can place the various recorders exactly where he wants them without having recourse to a troublesome forest of rods and clamps. I then added the lever and recording apparatus marked *e* in Figure 1, so that the slightest jarring of the clamp *h* would be magnified and recorded on the drum.

Solutions used in the burette. A number of fluids were used in the burette, such as plain water, soapy water, and slightly acid or alkaline solutions, but nothing seemed to be much more effective than Locke's solution. Slightly acid and slightly alkaline solutions

were somewhat more provocative of rushes, but I returned to the use of Locke's solution because it has the great advantage of being least injurious to the delicate mucosa of the bowel.

The importance of the column of fluid. That the presence of fluid in the lumen of the bowel helps in the production of rush waves was shown by the fact that when the segment of duodenum into which fluid was squirted was closed off from the bowel below by a band of tape applied just tightly enough to occlude the lumen, it was not so easy to start waves on their way down through the jejunum. Even less effective than squirts of fluid were electric and mechanical stimuli applied to the wall of the duodenum.

APPARATUS USED FOR RECORDING PERISTALSIS

The balloons commonly used by many workers constitute foreign bodies which are undesirable (1) because they obstruct the lumen of the bowel and thus interfere with the passage of rushes; (2) because the muscle keeps contracting powerfully in an effort to move the foreign body onward; (3) because, at least in the rabbit, the gut tends to gather on the tube leading to the recording apparatus, and (4) because there is considerable trauma where the cut is made for the insertion of the tube. Because of all these objections I long ago gave up the use of balloons as recording devices. I soon saw that if I were ever to succeed in recording the rush waves of the bowel, I must attach the apparatus to the peritoneal surface so as to leave the lumen clear. Accordingly, I fastened recorders of several types to the peritoneal coat (Alvarez and Mahoney). Although good records could thus be obtained, I was never quite satisfied because there was always some blocking of the passing waves due to the irritation and trauma produced by the little pinching clips.

"Circular" recording unsatisfactory. My dissatisfaction with existent methods of recording became acute some six years ago when my assistants and I found that although, to the unaided eye, it appeared that peristaltic rushes skipped a segment of bowel poisoned by nicotine, graphic records made by attaching threads and light levers to several points along the affected segment showed what looked like the passage of a normal rush.

Eventually it occurred to me that since we were recording movements of a loop of circular muscle gripped between two little wire clips, as in Figure 1, *a*, the pull of the lever on the empty bowel would tend to flatten it until its cross section would resemble that of a rubber band, and the distance between the two clips would represent approximately half of the circumference. When, however, the bowel had become filled and its cross section had become a circle, the distance between the clips would represent the diameter. Since the diameter is less than half of the corresponding circumference, one should expect, with this method of recording, to see the writing point of the lever rise when the gut filled, and calculation showed that the difference between the half of the circumference and the diameter, when magnified by the lever, should amount to about 3 cm. Actually, when loops of dead bowel were distended with water, this was the amplitude of the movement observed, and at last I saw why so many of the records obtained had been confusing or unintelligible.

A "longitudinal" recorder. In order to avoid the defect in the "circular" recording device, I designed the simple piece of apparatus pictured in Figure 1, *b*, and with it recorded movements of the longitudinal muscle. A small weight was usually placed on the short arm of the little lever so as to balance the moving part and make the apparatus more sensitive. Contractions of the muscle between the clips should depress the end of the first lever and produce a rise on the record.

As soon as I placed the new longitudinal enterographs on nicotinized segments of gut I was again puzzled to find, in most of the tracings, records of what looked like normal rushes, although, as I watched the bowel, I still failed to see any wave of contraction in the poisoned segment. Occasionally, distention of the bowel would produce the expected drop in the level of the record, but commonly it did not, and I was driven to the conclusion that the longitudinal enterographs must often respond to distention of the segment with a confusing upward movement of the writing point. This conclusion was supported by the results of an experiment in which a segment of dead bowel was distended with fluid. What happened, apparently, was that a segment of bowel, when filled, tended to form an arc because the length of the mesenteric side is fixed by connective tissue, and the antimesenteric side alone can stretch.

The distention recorder. When the longitudinal enterograph was found to be unsatisfactory, I next designed the "distention recorder," shown in Figure 1, *c* and *d*. It consists of two little bronze "hands" which hold the bowel between them. One is fixed and the other is movable. The pivot for the movable arm is taken from a heart lever made by the Harvard Apparatus Company. An upward movement of the upper "hand" or spatula, due to distention of the bowel, causes an upward movement of the writing tip of the lever. The illustration fails to show a little sliding weight usually placed on the arm near the attachment of the thread almost to balance the weight of the spatula. The little bobbin on the lever can be rotated to shorten the thread and to make necessary adjustments in the height of the record on the drum. A little bit of wire soldered to the movable arm of the recorder makes a tight crotch which serves to pinch and hold the lower end of the thread. These two very convenient, simple, and time-saving accessories were added by Dr. Joseph Berkson.

With the two little slightly curved spatulas holding the bowel gently between them, it seemed as if the passage of the smallest amount of fluid would have to be recorded as a rise in the level of the tracing, and actually, the excellence of the records obtained with this apparatus exceeded all my expectations. This recorder seemed to be more sensitive than either of the other two because when the three were placed side by side on a short segment of gut, the record of distention commonly revealed weak "long distance effects" and little surges of fluid up and down the bowel, which had not had any effect on the other two recorders.

This greater sensitiveness may perhaps be due to the fact that with this light instrument the bowel is not irritated or traumatized, and there is almost no obstruction to hold back or stop the progress of waves. In order to place the bowel between the blades of the

An Office Procedure for the Rapid Estimation of Pepsin and Its Clinical Significance*

By

HARRY BAROWSKY, M.D., HENRY TAUBER, Ph.D.†

and

ISRAEL S. KLEINER, Ph.D.

NEW YORK CITY

ESTIMATIONS of pepsin have not been commonly made in routine gastric analysis because of the lack of a convenient "office" method for its quantitative determination. The procedure utilizing Mett's tubes was the standard for a long time but it has now been given up by most workers (1). Several of the more recently described methods have gained favorable comment and are probably used to some extent. However, for most of them the preparation of the substrate is time-consuming if not difficult (2, 3). For others, very careful technique must be employed as well as apparatus not usually found in the practitioner's office (4, 5). There is obviously a need for a simple and rapid, yet reasonably accurate procedure. The method to be described meets these requirements; it employs no elaborate apparatus; and uses as a substrate milk treated with a buffer, which is easily prepared and which keeps indefinitely. With this method we have made several clinical observations, which are of considerable interest and importance.

METHOD FOR DETERMINATION OF PEPSIN IN GASTRIC JUICE

The method is based on the fact that the milk-clotting action of human gastric juice at a pH of 5.0 is really an early stage of proteolytic digestion of casein by pepsin and that there is no rennin in human gastric juice (6). In other words, milk-clotting under these conditions is a function of the pepsin molecule (7). Therefore the concentration of pepsin may be estimated by measuring the milk-clotting power of the gastric juice, using the strongly buffered milk as a substrate. The same principle is the basis of other methods (5, 8). Fresh cow's milk (raw or pasteurized) is employed and, when mixed with an equal volume of the buffer, becomes a substrate which is easily reproducible, and which rules out pH changes occurring in the milk and in the gastric juice.

Preparation of Standard Milk Substrate. The buffer is prepared by dissolving 42 g. of NaOH in about 500 c.c. of distilled water, adding 115 c.c. of 80% acetic acid and diluting to 1000 c.c. with distilled water. Fresh cow's milk is diluted with an equal volume of this buffer, 200 c.c. of the buffered milk is usually ample for one determination. This buffered milk, having a pH of 5.0, was first suggested by Ege and Menck-Thygesen (8).

Preparation of Gastric Juice. Three cubic centimeters of gastric juice (or less, if this amount is not available) are diluted with an equal volume of distilled water, mixed well and filtered.‡ One cubic centimeter of the filtrate is now diluted to 12.5 c.c., making a total dilution of 1:25, and one cubic centimeter is diluted to 25 c.c., a dilution of 1:50. A preliminary test is made to determine the approximate clotting power in the following manner: 10 c.c. of buffered milk are placed in each of two test-tubes and 1 c.c. of the 1:25 gastric juice is added to one and 1 c.c. of the 1:50 to the other. Both are placed in a water bath at 20° C.§ and watched for the first appearance of a clot. If the 1:25 does not clot the milk in 10 minutes, undiluted gastric juice is indicated for the final test. If the 1:25 clots in 5-10 minutes, this dilution is indicated, whereas if the 1:50 clots in 5-10 minutes this more diluted gastric juice is to be used. Ten tubes are now set up, each containing 10 c.c. of buffered milk, and placed in a water bath at 20° C. To these tubes are now added 0.1, 0.2, 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9 and 1.0 c.c. of the indicated diluted gastric juice, respectively. The contents of each of the tubes are quickly mixed and kept for 10 minutes at 20° C. The smallest amount which produces a clot is observed, and the number of cubic centimeters of milk clotted by one c.c. of gastric juice is calculated. Since we define a unit as the amount of pepsin which will clot one c.c. of buffered milk in 10 minutes at 20° C., the figure determined equals the number of units in the specimen.

Calculation:

Formula. Units of pepsin per c.c. original gastric juice $= \frac{1}{\text{volume diluted gastric juice}} \times$ degree of dilution x 10.

For example: If 0.6 c.c. 1:50 gastric juice is the smallest amount which will clot 10 c.c. buffered milk in 10 minutes, then 1/0.6 x 50 x 10 = 1.67 x 500 = 835 units per c.c. original gastric juice.

Test Meals: We have employed two types of test meals, i.e., plain and with meat. The former consists of eight arrow root biscuits and 600 c.c. water. The meat meal contains in addition 15 g. chopped lean beef, which had been boiled for one hour in 500 c.c. of water.

†Now in the Research Department of The McLeod Infirmary, Florence, S. C.

Submitted March 17, 1937.

‡In achylia gastrica cases, however, the original gastric juice is diluted with an equal volume of 0.1 N HCl instead of water before filtration to activate any inactive pepsinogen which may be present. Here no further dilution may be necessary and several cubic centimeters of the acidified gastric juice may have to be used. Even then no clot may occur. If there is a suspicion that regurgitation has taken place, the determination is likely to be inaccurate since trypsin reacts similarly to pepsin. All of our patients had been intubated several times previous to these tests and consequently regurgitation was quite unlikely. If the presence of trypsin can not be avoided, one of the more elaborate procedures for the estimation of pepsin must be used.

§A cup or tumbler of tap water will ordinarily answer the purpose, since tap water is usually about this temperature.

time the intestinal contents are moving slowly out of the segment. But even when the bowel is apparently normal and rushes are good, they do not all produce good narrow "steeples."

The peak made by the passage of a rush wave through the segment of bowel lying within the two spatulas of the distention recorder is commonly sharper at the top and narrower at the base than that made by the other two recorders on the circular and longitudinal muscles, which indicates that the muscle remains contracted and active for some time after the loop empties. This tendency of the bowel to remain contracted for several seconds after a rush wave has passed was plainly apparent in the motion pictures of peristalsis made and studied by Zimmermann and me, and its value in preventing regurgitation of intestinal contents orad was pointed out by us.

As the observer watches a rush he often gains the impression that the wave was not sequent but that several rushes took place along the bowel about the same time, and the records may show that this actually was the case. As I said before, when the stimulus is thrown into the duodenum, an impulse of some kind shoots down the length of the intestine. Responding promptly to this fast traveling stimulus, some segments of bowel begin to contract three or four seconds before the arrival of the main wave, much as a runner in a relay race will get under way before his team-mate arrives. For convenience I speak of the phenomenon as "anticipation."

The "long distance" stimuli also cause little surges to take place along the bowel. These are revealed as little rises in the records of distention, due to the entrance of a little fluid into a segment. These rises may appear from five to ten seconds before the main column comes rushing in.

Fortunately, now, by putting distention recorders at the oral and caudal ends of a short segment, with circular and longitudinal recorders in between, one can tell when fluid enters and leaves the segment and one can study the reaction of the muscle of the bowel to the presence of such fluid. Only rarely did I see what might be interpreted as signs of relaxation or inhibition in the longitudinal or circular records at times when I could be sure that the fall in the level of the record was not due to distention caused by the entrance of fluid into the segment.

THE SEVERAL PEAKS ON A WAVE

A peristaltic rush, no matter how powerful, does not empty the small bowel from one end to the other; it seems to push material ahead for a short distance only to drop it and pick up more further on. As a result, the main crest of the wave is often followed by one or more "scavenging waves" which serve to move fluid out of segments that have been left somewhat distended. Curiously, the interval of time between any two peaks on a wave, as it travels from one end of the bowel to the other, is often kept remarkably constant. Occasionally, the record will show that one of the several peaks was made by a little surge that ran orad for some distance while the main wave was going on caudad.

To show how complicated a rush can be, I will describe an actual record made as a wave passed a set of four recorders. First, about twenty-five seconds before the main column of fluid arrived, there were signs of inhibition, with a lessening of the amplitude of the rhythmic contractions; second, one rhythmic contraction was entirely blocked; third, there was distention of the segment due to the passage of a small amount of fluid; fourth, there was contraction of the muscle; fifth, there was marked distention produced by the passage of the main column of fluid, and sixth, there came the final contraction that emptied the segment.

WATER WAVES

Occasionally, when a long segment of poorly functioning bowel failed to empty itself of the fluid squirted in, I could see in the distention records, made simultaneously at several points along the length of the segment, what I call a "water wave"; that is, a small peak like that of an artefact, appearing everywhere at the same time, and due apparently to a disturbance transmitted through the fluid. Such water waves might easily lead to false interpretations if the experimenter were to interpret them as signs of rapid nerve conduction. They can be avoided either by not allowing the bowel to fill with fluids, or by placing a bit of tape around the bowel, just tight enough to obstruct the lumen.

SUMMARY

A simple apparatus is described for squirting, with measured force, a measured amount of fluid into the duodenum. In normal rabbits, each such stimulus usually produced a peristaltic rush. It did not seem to make much difference what type of fluid was injected.

Two enterographs, attached to the peritoneal coat and designed to record separately the movements of the circular and the longitudinal muscles, produced tracings which, while helpful, were not satisfactory for reasons that have been given in this paper. Accordingly, a new enterograph was devised which records principally distention of the bowel and the passage of fluid through the lumen. It has the great advantage of not traumatizing, irritating, or obstructing the bowel.

Records obtained with this apparatus helped to differentiate normal and atypical or pseudo-rushes. The normal rush produced in the record sharp peaks which were due to a rapid distention of the bowel, followed by a prompt contraction of the muscle and emptying of the segment. Abnormal rushes tended to produce a somewhat flat-topped elevation in the record, due to slow and deficient emptying of the bowel.

What looks like a rush may be a series of contractions or short waves which appear simultaneously at several points along the bowel. Rushes are commonly made up of several little surges and waves.

After a large rush wave passes, there are usually one or more small "scavenging waves" which serve to empty the bowel. Sometimes there are also little surges running orad for a short distance.

Disturbances commonly appear in a segment of bowel from three to ten seconds before a rush arrives. They consist usually of increases in tonus and activity, but occasionally some inhibition can be detected.

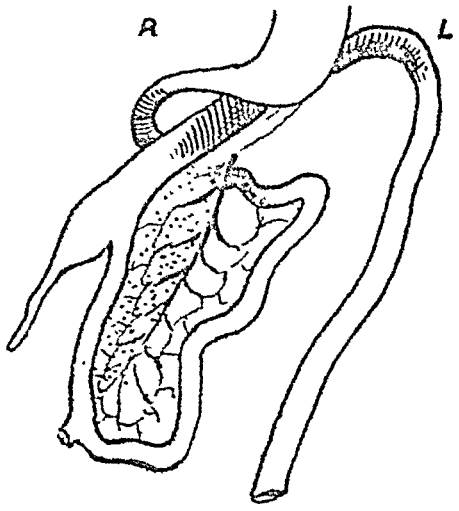

Fig. 3. The rotation of the midgut is completed, the different portions of the intestinal tract are about in their permanent positions.

short distance from each other forming the "duodeno-colic isthmus."

During the further growth of the midgut, the abdominal cavity becomes too small to harbor all the fast growing intestinal loops and a temporary physiological umbilical herniation is formed containing a large portion of the midgut. This is the situation about at the tenth week and within the next week the following important development occurs: The small intestines reenter the abdominal cavity beginning from the proximal (duodenal) end and followed by the distal loops (jejunum and ileum) and finally by the cecum and ascending colon. The loops slide behind the mesenteric artery (see Fig. 2), thereby forming the duodeno-jejunal flexure. The upper jejunal loops occupy the left upper abdomen pushing the splenic portion of the colon upwards and towards the left side into its permanent position. After the lower ileal loops reenter, the cecum and ascending colon are placed in the right upper quadrant (see Fig. 3).

During the late months of pregnancy the cecum reaches its permanent position in the right iliac fossa by descent and longitudinal growth. All portions of the colon then become fixed in position by fusion of the mesenteric folds with the posterior peritoneum.

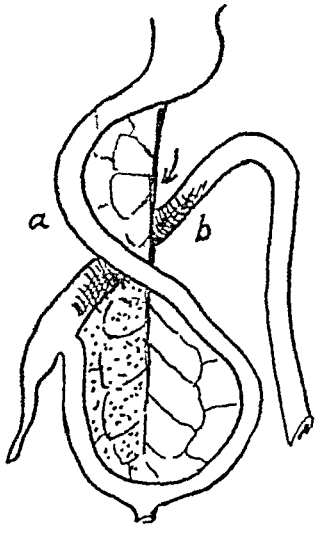

Fig. 4. Reversed rotation. The lower ileum and proximal colon reenter first thereby rotating the midgut in the reversed direction. The duodenum (a) is in front, the transverse colon (b) is behind and trapped at its middle (arrow) by the stem of the superior mesenteric artery.

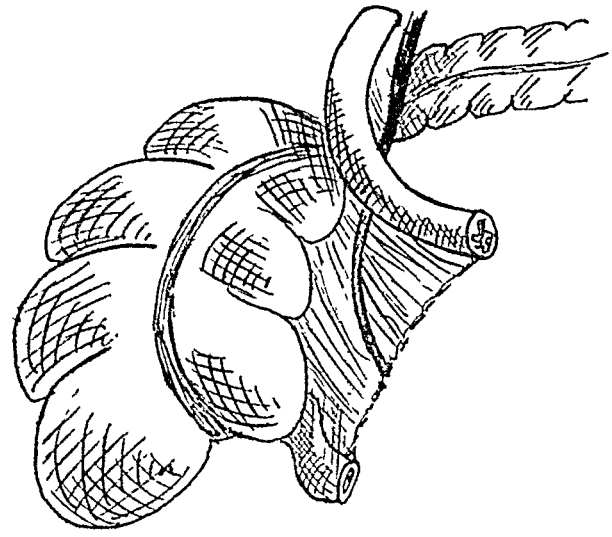

Fig. 5. Operative findings in a case of reversed rotation which lead to acute intestinal obstruction. The findings correspond exactly with the anatomical situation in Fig. 4. Note the dilatation of the proximal and the collapse of the distal colon. (after GARDNER and HART. *Arch. of Surg.*, 29:952, 1934).

ANOMALIES OF ROTATION

A review of the literature reveals that practically all the abnormalities occur in the midgut, while malformations in the foregut and hindgut are considered as extremely rare. However, not as much attention has been paid to these portions and it is possible that further study will reveal changes corresponding to those in the midgut.

Disturbances in the normal development of the mid-

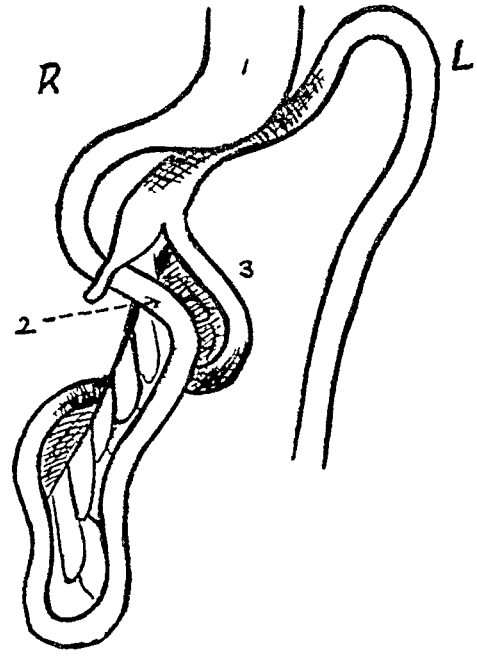

Fig. 6. Malrotation. The proximal and the distal part of the midgut reenter the abdominal cavity at the same time, the former in front, the latter behind the artery. The duodenum (2) and the lowermost loop of the ileum (3) are placed side by side. The cecum is in a subpyloric position.

Gastric samples: The Rehfuss method of extraction was employed. Pepsin was determined in samples obtained 15, 75 and 120 minutes, respectively, after the ingestion of the meal. Free HCl and total acidity were also titrated.

TABLE I

Typical normal response

Time	Free HCl	Pepsin	Free HCl	Pepsin
min. after meal	c.c. N/100 per c.c.	units per c.c.	c.c. N/100 per c.c.	units per c.c.
	Plain Meal		Meat Meal	
15	0	70	4	700
30	10		10	
45	24		14	
60	32		18	
75	30	660	28	1000
90	20		30	
105	30		36	
120	26	1000	20	1200

Tests were performed on 15 individuals, comprising several normal persons and a number suffering from gastric disorders. Twelve pepsin determinations were made in each case, a total of 180 determinations. They have been divided according to their free HCl secretory curves into four groups:

1. Euchlorhydria (free HCl 20-40).
2. Hypochlorhydria (free HCl below 20).
3. Achlorhydria and Achylia (no free HCl).
4. Hyperchlorhydria (free HCl above 40).

TABLE II

Case of hypochlorhydria. Patient J. D.

Time	Free HCl	Pepsin	Free HCl	Pepsin
min. after meal	c.c. N/100 per c.c.	units per c.c.	c.c. N/100 per c.c.	units per c.c.
	Plain Meal		Meat Meal	
15	0	1000	0	300
30	0		0	
45	0		6	
60	0		6	
75	18	800	24	800
90	10		26	
105	16		36	
120	30	1300	32	2400

In the normal or euchlorhydria group, the first samples, obtained 15 minutes after ingestion of the test meal, were relatively low in peptic power, although all were above 300 units. A marked rise then occurred, the 75 minute samples showing a content of over 1000 units in most cases. This high peptic power was usually maintained to the end of the two hour period, but when it varied much the variation as a rule paralleled the fluctuation of the free HCl. The meat meal usually produced a higher pepsin content than the meatless meal. This is well shown in the typical experiment summarized in Table I.

TABLE III

Case of achylia. Patient R. M.

Time	Free HCl	Pepsin	Free HCl	Pepsin
min. after meal	c.c. N/100 per c.c.	units per c.c.	c.c. N/100 per c.c.	units per c.c.
	Plain Meal		Meat Meal	
15	0	20	0	10
30	0		0	
45	0		0	
60	0		0	
75	0	100	0	Pepsinogen 4 Pepsin 8
90	0		0	
105	0		0	
120	0	8	0	40

In the hypochlorhydria group the peptic activity was not diminished as a rule. Although the free HCl was minimal in amount, there was often seen a rough parallellism between the free HCl and the amount of pepsin present. (See Table II).

The achlorhydria and achylia group consisted of cases of mucus gastritis, atrophic gastritis, and one case of pernicious anemia with achylia. It is noteworthy that an absence of pepsin was seldom, or never seen, even in cases showing no free HCl throughout the two hour period. A typical example is shown in Table III.

TABLE IV

Case of hyperacidity. Patient J. R. M.

Time	Free HCl	Pepsin	Free HCl	Pepsin
min. after meal	c.c. N/100 per c.c.	units per c.c.	c.c. N/100 per c.c.	units per c.c.
	Plain Meal		Meat Meal	
15	0	330	30	600
30	54		38	
45	45		30	
60	60		43	
75	56	2000	34	2000
90	56		40	
105	70		40	
120	50	2000	30	2000

There are several points which deserve some empha-

sis. In the first place, the concentration of pepsin is independent of that of free HCl. However, in any given case the two values usually run more or less parallel. Secondly, pepsin or pepsinogen was demonstrable in nearly every sample tested, even when no HCl was present. Rockus, Bank, and Willard (9), after injecting histamine, found "gastric rennet" (which must now be considered to be pepsin) and no HCl present in seventeen out of sixty-four cases. These they term "true achlorhydrias," instead of the more usual expression "true achylias." They also conclude that "the secretion of gastric enzymes apparently persists in many stomachs after acid secretion has stopped." Thus the usually accepted distinction between achylia and achlorhydria becomes more difficult to make. An achlorhydria has usually been considered a case in which HCl is lacking but in which the enzymes may be present. In achylia, on the other hand, neither acid nor enzyme is present, according to the usual classification. Now, if the enzyme is seldom, if ever, completely absent—as appears to be the case when our delicate method is employed—then either the term achylia must be dropped, or a new definition be found. The explanation of the persistence of pepsin lies, of course, in the evident fact that although the parietal cells may be destroyed some chief cells continue to be active even in advanced cases of "achylia."

The addition of cooked meat to the test-meal produced, in all cases except the achylias, an increased content of pepsin in the gastric juice. Many substances, including raw meat, are known to increase the flow of gastric juice when introduced into the stomach. In our experiments, however, is seen a different phenomenon, i.e., a change in the concentration of the enzyme as a result of a definite stimulus, presumably chemical in nature.

SUMMARY

1. This method is simple, accurate and rapid. It can easily be used as an office procedure.

2. It is extremely sensitive, as small amounts of pepsin may be detected.

3. Peptic activity apparently seems to run parallel to HCl secretion in all cases except those in the Achylia group.

4. In Achylia gastrica, it seems that pepsinogen or pepsin is still secreted despite the fact that HCl is not present.

5. Meat usually produces a definite increase in peptic activity in all groups except the achylias.

Abnormalities of the Rotation of the Midgut: a Report of Four Cases*

By

GERHARD DANELIUS, M.D.

CHICAGO, ILLINOIS

THE faulty rotation of the midgut, leading to abnormal position of the intestines, is a congenital anomaly due to a disturbance in the normal embryological development of the intestinal tract. The thorough knowledge of its different variations is not of a mere theoretical interest but of great practical consequence since grave complications may occur at any time. The previous knowledge of the anatomical situation may clear up indistinct clinical pictures and may facilitate necessary interventions or avoid unnecessary operations. The only means of diagnosing the condition before operation is by roentgenologic study with the exception of the newborn, in whom the anomaly may be suspected from the clinical course.

While the anatomical condition was known to the anatomists for about a hundred years, the first correct diagnosis on the living patient before operation was made only as recently as 1924 by Altschul (1). The clinical picture produced by the abnormal rotation of the midgut ("mesenterium commune" of the European

literature) varies from very slight abdominal discomfort to true acute intestinal obstruction, therefore it is essential to be familiar with all its anatomical features and clinical symptoms. Although I believe, that the condition is not extremely rare, a review of the world literature has revealed only about 120 cases. It is probable, that a considerable number of cases have been observed but have not been reported.

EMBRYOLOGY

The exact knowledge of the embryological situation is indispensable and can be best obtained from the classical description by Norman Dott (8). In 1934, Gardner and Hard (10) published an extensive and beautifully illustrated paper on this subject.

At the 5th week of embryonic life the intestinal canal is a longitudinal tube fixed to the posterior wall of the abdominal cavity by the mesenteric plate, both being oriented in the vertical direction and in the sagittal plane. At this time the intestinal canal is subdivided into (1) foregut supplied by the celiac axis, (2) midgut supplied by the superior mesenteric artery and (3) hindgut supplied by the inferior mesenteric artery. From the foregut is derived the abdominal part of the esophagus, the stomach and the duodenum down to a point just below the papilla of Vater. The midgut forms the distal portion of the duodenum, the small intestines and the large bowel as far as the middle of the transverse colon. From the hindgut the rest of the large bowel is derived (see Fig. 1a).

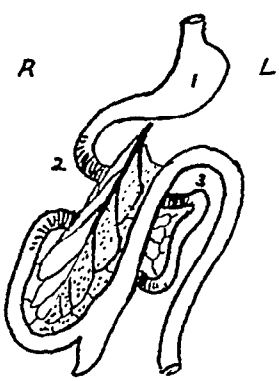

Fig. 2. Normal development about at the 10th week. The proximal jejunum reenters the abdominal cavity sliding behind the stem of the mesenteric artery. The duodeno-jejunal flexure is formed. (1) stomach. (2) duodenum. (3) duodeno-jejunal flexure.

At the middle of the midgut the omphalomesenteric duct is found and opposite its origin the superior mesenteric artery divides into its terminal branches. The midgut and its mesentery are divided into the prearterial and the postarterial segment. Distally from the middle of the gut a bud is formed for the later development of the cecum. The midgut grows much faster than the other portions of the intestinal tract, especially at its prearterial segment which forms all the loops of the small bowel except the lower ileum.

With the so called first rotation the midgut and its mesentery are placed from the sagittal into the frontal plane thereby locating the duodenum and small intestines into the right side, and the colon into the left side of the abdominal cavity (see Fig. 1a). At the same time the foregut performs a rotation whereby the pyloric portion of the stomach is directed towards the right side, the anterior wall (larger curvature) downwards and to the left, the posterior wall (lesser curvature) upwards and to the right.

The two footpoints of the midgut, located at the middle of the duodenum and the middle of the transverse colon, become fixed with the posterior peritoneum at a rather

Fig. 9. Nonrotation of the midgut (Case 4). Observation of Dr. Max-Cohn. The colon is visualized by means of a barium enema. All the typical findings of nonrotation are present.

symptoms and clinically healthy. From the papers published up to date it is not possible to get reliable information about their percentage. The anomaly is found accidentally during an abdominal operation or as a true leftsided appendicitis or as a surprise at necropsy.

Group 2. A large group of patients describe upon questioning vague gastro-intestinal symptoms such as discomfort, moderate pain, a feeling of vague pressure, belching and sometimes mild constipation. Another group complains of occasional sudden attacks of marked abdominal pain not well localized and vomiting. There are always long periods of complete health interrupted by the above reported attacks. It is not possible clinically to make the diagnosis or even to suspect the malformation. The patients report in the X-ray department with clinical diagnoses such as "possible gastric or duodenal ulcer," "rule out carcinoma" or merely "unclear abdominal complaints."

Group 3. Acute intestinal obstruction may occur at any age, cases having been reported in the first days of life and as late as 76 years. The long common mesentery is prone to form a volvulus, turns up to 450° having been described (8). Previous symptoms are present in the majority of cases but may be completely absent. One group presents symptoms from early youth — that is repeated attacks of pain with vomiting which always clear up spontaneously — the patients may be slightly underdeveloped. Obstruction occurs in adolescence particularly around the 15th to the 18th year. This history points towards malrotation or reversed rotation rather than towards nonrotation. The findings in reversed rotation show a typical location, as the obstruction is found in the middle of the transverse colon at the point where the colon is trapped behind the stem of the mesenteric artery (see Fig. 5). Patients showing their first symptoms later in adult life are usually cases of nonrotation. In all varieties cases are reported, in which operative treatment gave excellent results with complete disappearance of all the symptoms.

Group 4. High intestinal (duodenal) obstruction of the newborn in abnormal rotation becomes evident around the 3rd to the 8th day of life. The infant becomes acutely ill and vomits ½ to 1 hour after feeding. Due to the location of the stenosis below the papilla of Vater *the stomach contents are bile stained and the stools become gradually colorless.* The upper abdomen is distended, the lower scaphoid and the child looks dehydrated. Clinically differentiation from congenital atresia of the duodenum is impossible, while the differential diagnosis of pyloric stenosis and abnormal rotation of the midgut is presented in the following chart:

	onset	time betw. feeding and vomit.	gastric contents
Pyloric stenosis	3-4 weeks	a few minutes	colorless
Common mesentery	3-8 days	½-1 hour	bile stained

The majority of these cases showed adhesions between the lower duodenum and the last loop of ileum due to malrotation. Occasionally, nonrotation or reversed rotation was found. If intervention is not practised the condition is usually fatal. Operations (gastro-enterostomy) on the newborn have been reported with complete recovery. The condition is sometimes reported as "abnormal bands" at the duodenum, the underlying abnormality having escaped recognition.

ROENTGENOLOGICAL CONSIDERATIONS

Roentgenological diagnosis of abnormalities in the rotation of the midgut is very easy and is usually made at the first glance. On examination of the stomach we observe the barium passing through the duodenum filling the upper jejunal loops without forming the duodeno-jejunal flexure (see Fig. 7). The jejunal loops occupy only the right side of the abdomen, the left side remaining completely empty. In case a barium enema was given first, the colon is found within the left and middle region of the abdomen, the cecum higher or lower at the midline. Except in some very rare cases of reversed rotation, where, roentgenologically, the large bowel may appear in its normal position, with either method of examination the condition cannot be overlooked by a fluoroscopist acquainted with the abnormality. After the diagnosis is made, the following points have to be cleared up: (1) The exact variety of the malformation (nonrotation, reversed rotation, malrotation) has to be determined. (2) The lowermost loop of ileum has to be located and its position in regard to cecum and duodenum determined. (3) Cecum and appendix have to be located. In case that the large bowel is found approximately in its normal position, the relation between the duodenum (anteriorly) and the colon (posteriorly) has to be demonstrated.

From our experience it is difficult to demonstrate all points of interest on a single film, and even with a cooperative patient the results may be disappointing. The following procedure in our hands gave the best results: After the preliminary diagnosis is made, the examination is discontinued and we wait for clear

Fig. 7. Nonrotation of the midgut (Case 3). Film taken 10 minutes after administration of a barium meal permits certain diagnosis of abnormal rotation of the midgut. Note the normal position of the stomach, the lack of the duodeno-jejunal flexure and the position of the small bowel within the right side only.

gut are of three different kinds: (a) nonrotation, (b) reversed rotation, (c) malrotation.

(a) *Nonrotation* is in its essential appearance best illustrated by comparison of Fig. 1a, b and c. In the patient with this type of abnormality the portion of the intestinal tract which is derived from the midgut is found in exactly the same position as in an embryo 8 weeks of age. The typical anatomical findings are:

(1) Lack of the duodeno-jejunal flexure.

(2) Position of the small intestines in the right side of the abdomen.

(3) Position of the whole large bowel in the left side of the abdomen.

(4) Location of the appendix at the midline or in the left side of the abdomen.

(5) Crossing of the last loop of ileum over the midline from the right to the left side of the abdomen to join with the right medial border of the cecum.

(b) *Reversed rotation.* In this state the loops of the midgut reenter the peritoneal cavity in the wrong order. The postarterial segment—i.e. the ascending colon, then the cecum, then the lower ileum—enters first and is followed by the prearterial portion, thereby resulting in a rotation of the midgut which is exactly the reverse of the normal. The position now obtained is characterized by the following anatomical findings: (See Figs. 4 and 5).

(1) Position of the duodenum in front of the large bowel and the mesenteric artery, lack of duodeno-jejunal flexure.

(2) Position of the mesenteric artery in front of the colon.

(3) Circumscribed narrowing at the middle of the transverse colon which is trapped here behind the stem of the mesenteric artery.

(4) Normal position of the other portions of the intestines.

(c) *Malrotation.* This condition occurs in the cases where the prearterial and the postarterial segments reenter the abdominal cavity at the same time, the former in front and the latter behind the mesenteric artery. The characteristic *anatomical findings* are: (See Fig. 6).

(1) Position of duodenum and upper jejunal loops (prearterial segment) in front of colon and mesenteric artery.

(2) Position of the lower small intestinal loops behind the mesenteric artery as in the normal patient.

(3) Position of duodenum and terminal ileum side by side often fixed by extensive adhesions.

(4) Presence of a very long and very narrow mesenteric pedicle, on which the whole small intestines and the proximal colon (former midgut) are freely suspended.

(5) Position of the cecum in the subpyloric region.

Anomalies of the rotation of the midgut have to be strictly differentiated from situs inversus abdominalis. The latter is merely an exact reflexion image of the normal. Sandera (21) has described a very unique case of a patient in whom both conditions were present simultaneously. Familial occurrence of mesenterium commune has been reported by Spitz (23).

CLINICAL PICTURE

Considering the common underlying pathology the variety of the clinical picture is astonishing. A subdivision into 4 main groups is possible:

Group 1 shows complete absence of any clinical symptoms.

Group 2 presents gastro-intestinal disturbances of moderate degree over a shorter or longer period of time.

Group 3 presents acute intestinal obstruction.

Group 4 comprises the high duodenal obstruction of the newborn.

Group 1. There seems to be no doubt, that a considerable number of patients are absolutely free of

Fig. 8. Nonrotation of the midgut (Case 2). *All points* of interest are visualized on one film. (a) duodenum leading directly to the upper jejunal loops in the right side. (bb) last loop of ileum crossing the midline. The appendix (arrow) visualized within the left lower quadrant. The small bowel is within the right, the large bowel within the left side of the abdomen.

Proctoscopic examination was negative.

A barium enema was negative.

On September sixteenth, the blood count dropped to 2,800,000 red cells with 45% hemoglobin. The following day, a soft, transverse body, three centimeters above the umbilicus which felt like a normal, hollow viscus was noted. There was also complete papillary atrophy of the tongue. Vomiting persisted. On September eighteenth, a rather soft, not tender mass about three by two inches was felt to the right of the umbilicus and indefinitely outlined, which gave the impression of changing size and shape under examining fingers. This mass was fairly movable, and it was thought it might be distended loops of small bowel. In the next few days, this mass became much more definite and increased in size but it was still thought to be a distended hollow viscus.

On September twenty-fifth, it was concluded that with a story of evanescent tumor together with vomiting and X-ray evidence of dilated duodenum, it was most likely the lesion was an obstruction high in the intestinal canal probably in the third portion of the duodenum or upper jejunum and that exploration was advisable.

On September twenty-eighth, under gas anaesthesia, patient was operated upon by Drs. Holman and Poth. A normal appearing stomach presented. The duodenal outlines were rather indefinite at first and there was a large, soft mass in the duodenal region directed down toward the ligament of Treitz. The pancreas, kidneys, and pelvic organs were normal. The transverse colon was then delivered into the wound and after that the jejunum distal to Treitz's ligament was brought up. It was found to be quite large and thickened, about eight centimeters in diameter and contained a large, freely movable, soft mass. Further examination of the duodenum showed it to be freely movable, very large, and at its proximal third there was an invagination of the duodenum into itself. The intussusception was then reduced. At the junction between the proximal and middle third of the duodenum there was a dimpled area on the anterior surface. Examination of the biliary tract showed the common duct to be dilated and entering the duodenum distal to the point of this dimpling. The gall bladder was large but contained no stones. The duodenum was then split over the dimple and a large sessile polyp made up of multiple polypi was delivered. This was then excised, leaving a margin of about one centimeter of normal bowel entirely surrounding it. The defect in the duodenum was then closed transversely. The defect in the duodenum included about two-thirds of its circumference. The great omentum was brought up and tacked to the line of sutures to aid in preventing subsequent intussusception.

Patient was returned to the ward in good condition. She had a rather stormy post-operative course with considerable difficulty in taking her food, persistent vomiting for seventeen days postoperatively, but with a high-caloric, high vitamine diet, liver extract, frequent transfusions, glucose and salt solution, she gradually improved. However, during this period the anemia persisted, the blood ranging around 52% hemoglobin with 2,880,000 red cells. There was some generalized edema and blood proteins were found at 3.85 grams per 100 c.c.

On November twenty-fifth, she was eating quite well, the edema was decreasing, the tongue was still quite smooth, but in spite of transfusions, iron, and liver, the blood remained at about the same level, the blood proteins also remaining low. On December third, she was dismissed from the hospital on a high protein, high vitamin diet with instructions to take lextron, three pills three times per day.

In July, 1936, she was seen at the clinic; her appetite was excellent, she had gained to one hundred forty-eight pounds, and the tongue was not smooth. A blood count showed 65% hemoglobin with 3,480,000 red cells; 36% hematocrit with a diameter of 8.3 microns. The stormy and prolonged post-operative period was largely due to the complicating deficiency states following many months of poor diet.

Gross Specimen: Consists of a cauliflower-like, grey, formalin fixed tumor with a small piece of bowel well attached. The tumor measures 9 x 8 x 4 centimeters and weighs 56 grams. The surface is roughened but velvety in appearance. Cut section shows the papillomatous nature of the specimen. The bowel wall although somewhat thickened appears normal.

Histological Examination: Shows columnar epithelium with many goblet cells thrown up into the folds which radiate out from a central fibrous stalk. The epithelial cells are irregular, well circumscribed, showing no mitosis and no extension into the underlying tissue. In the submucosa are seen normal appearing Brunner's glands. The blood vessels are dilated, many of which are filled with red blood cells. There is no evidence of malignancy. The diagnosis is Papilloma, adenomatous (duodenum).

DISCUSSION

In Chart I we have tabulated the essential findings in these cases. From this review, it is evident that duodenal intussusception occurs in both males and females in an age ranging from twenty-one to seventy-five years. Symptoms were present from four to twelve months before being relieved by surgery or terminating in death. The outstanding symptom has been vomiting, occurring irregularly after meals and starting usually intermittently but becoming more frequent and more severe. Pain may or may not be present. Weakness and loss of weight are marked. Physical signs other than emaciation may be absent but the finding of a tumor in the upper abdomen, especially if it is inconstant in appearance and variable in size and shape, should make one suspect intussusception.

Of the laboratory findings, occult blood in the stools and anemia are apparently constant.

X-ray examination has so far proven disappointing primarily because the significance of the finding was not appreciated. In Kellogg's case, the barium shadow of the dilated duodenum is interrupted by a spherical mass surrounded by a ring of barium which as Kellogg (2) reports was described by Carmen as typical of tumor formation but which was interpreted in this case as obstruction due to adhesions.

In Case VII, there was abrupt termination of the barium shadow of the markedly distended loop of duodenum and yet the X-ray department reported that no pathology could be demonstrated. In their subsequent report the fact that the obstruction was inconstant made diagnosis difficult for the possibility of intussusception was not considered.

In all but one of these cases a benign tumor was the exciting factor in the development of the intussusception. Tumor of the bowel is recognized as one of the primary etiological factors in the production of intussusception in adults. Benign tumors of the duodenum account for only about five per cent of the benign tumors of the bowel. Frequently, no symptoms are produced but as reported by Balfour and Henderson (9) in a study of fourteen cases, benign tumors of the duodenum may be responsible for serious symptoms, particularly hemorrhage. Raiford (10), in a report of forty-eight benign tumors of the small intestine found ten in the duodenum. He states that "invagination seldom occurs and symptoms when present are brought on by encroachment of the tumor mass upon

working conditions. The night before the examination the patient takes one full barium meal mixed with one tablespoonful of epsom salts in order that the cecum and the appendix may be visualized. Often a good regular filling of the whole large bowel is hereby obtained. On the following morning one-third of a barium meal is administered, the passage of which is observed by repeated fluoroscopic examinations. As soon as the junction of the lowermost ileum with the cecum is visualized, another third of a meal is given, to show stomach, duodenum and upper jejunum. If necessary, the lowermost portions of the colon can be filled by a small barium enema. Repeated observations are necessary. The smaller the amount of barium given, the clearer the situation is visualized. In cases of intestinal obstruction this plan has to be changed according to the symptoms and the general condition of the patient. If the above described technique fails, it is advisable to watch the passage of a contrast meal and to give a barium enema plating the different points of interest successively.

REPORT OF FOUR CASES

Case 1. Male, age 20 years. The patient was in perfect health and without any abdominal complaints up until 3 years ago. Since then he suffered from cramplike pains in the epigastrium coming about 3 hours after meals. Occasionally the pain was present at night. Sodium bicarbonate gave immediate relief. Vomiting, belching and acid eructations were present. He also had the typical periods of freedom from symptoms experienced by the peptic ulcer patients. X-ray examination (5/7/1935) revealed an irregular and narrowed duodenal cap with a true ulcer niche at its lesser curvature towards the base. In addition we found an absence of the duodeno-jejunal flexure and in following up the case the typical picture of a nonrotation of the midgut (see Fig. 1c).

In this case all the symptoms are best explained by the presence of the duodenal ulcer, and it is reasonable to assume that the anomaly of the midgut is not responsible for the complaints of the patient.

Case 2. Female, age 41 years. The patient was in good health and without any abdominal complaints up until 4 years ago. Since that time she complained of severe cramplike abdominal pain localized in the left lower quadrant and radiating towards the back. Together with the pain tenesmus was present. While generally moderate constipation prevailed there were attacks of diarrhea. The pains were occasionally very strong and often lasted for six hours. There was no nausea, belching or vomiting nor any connection of the pain with the intake of food. Occasionally the described symptoms ceased for one or two weeks but always recurred. Hysterectomy performed 3 years ago did not relieve the symptoms. The clinical diagnosis was: Spastic colitis, malignancy to be ruled out.

X-ray examination (12/5/1935) revealed the typical picture of an abnormal rotation of the midgut. In this case it was possible to visualize all the points of interest including the filled appendix on one single film (see Fig. 8). Except for the malformation repeated examinations of the colon did not reveal any organic pathology of the colon or the appendix.

It is probable, that the rather severe symptoms of the patient were due to the intestinal malformation since clinically, surgically and roentgenologically there were no evidences of other pathology. Since the symptomatology is mainly colonic and especially since at several occasions the proximal colon seemed to be moderately widened, the possibility of a reversed rotation was seriously considered.

Case 3. Male, age 38 years. 13 years ago the patient complained of occasional epigastric distress with moderate pain occurring usually after eating. This lasted for a few months to disappear completely. For the last 5 months the above described symptoms were present but more pronounced. The patient felt nauseated but did not belch or vomit. X-ray examination (4/23/1936) (see Fig. 7) revealed a typical nonrotation of the midgut and no further intestinal pathology. The appendix was well visualized in the left lower quadrant.

As on repeated examination no further pathological findings could be demonstrated, it is probable, that the mild chronic symptoms were due to the intestinal anomaly.

Case 4. An X-ray picture of a young male patient, examined by Dr. Max-Cohn is added; it presents all the typical signs of a non rotated midgut (see Fig. 9).

SUMMARY

The embryological phases of the development of the intestinal tract are reviewed with special reference to the normal and abnormal rotations occurring in the midgut. The different clinical pictures are discussed. Mesenterium commune is not a mere abnormality, but may lead to intestinal obstruction, incomplete volvulus or to difficult diagnostic problems in case of a true leftsided appendicitis. A roentgenological technique adequate to demonstrate the condition is described. A report of four observations is given.

Further Refinements in the Method of Administering Colon Bacillus Vaccine Therapy, and in the Therapeutic Use of Sodium Ricinoleate

(As Related to Chronic Functional Diarrhea, Chronic Headache, Chronic "Toxic Vertigo" and the "Unstable Colon")*

By

JOHN G. MATEER, M.D.

and

JAMES I. BALTZ, M.D.

DETROIT, MICHIGAN

INTRODUCTION

IN an earlier publication (1), the authors presented in comprehensive form the various indications and contra-indications for, and the limitations of, colon bacillus vaccine therapy. The methods of preparation and administration of detoxified B. coli vaccine were outlined. In four groups of cases, the therapeutic results definitely due to colon bacillus vaccine therapy were tabulated statistically. These four groups included, (1), the chronic functional diarrheas, (2), chronic headaches of the type associated with chronic constipation or colon distress, (3), cases of "toxic vertigo," and, (4), a group of "unstable colon" (non-ulcerative colitis) cases. Convincing results were obtained from B. coli vaccine therapy in groups of such patients whose symptoms had not disappeared following employment of the usual therapeutic measures. From these and other observations, the conclusion was reached that colon bacillus vaccine therapy, if judiciously used in properly selected cases, with avoidance of overdosage, constitutes a valuable therapeutic aid. Although the various observations and deductions outlined in the previous comprehensive publication will not be reviewed in this publication, one should be thoroughly conversant with them before employing this type of vaccine therapy.

It is important to emphasize that, in the above four related groups of cases, it is customary after diagnostic study to institute first a comprehensive plan of therapy. Colon bacillus vaccine therapy is reserved for those patients who have not obtained a satisfactory result from the above therapeutic program. The comprehensive plan has consisted of, (1), eliminating, as far as possible, the various etiological factors contributing to nervous tension, (2), the correction of any other faulty habits, (3), obtaining a diet diary from the patient, which permits the elimination of probable aggravating articles of food, and the provision of adequate vitamines and a proper balancing of the diet, (4), physiological regulation of the bowels, (5), the temporary use of a simple nerve sedative (if indicated), and, finally, (6), the therapeutic use of sodium ricinoleate ("Soricin"). In the "unstable colon" group of cases, the use of belladonna or atropine for the symptomatic relief of colon distress no longer is necessary, except in occasional cases.

Since the last publication, two important advances in the therapeutic management of the four above-mentioned groups of cases have been made. First, the routine use of sodium ricinoleate in larger doses than formerly used has proven to be of great therapeutic aid in all four types of cases, and has reduced definitely the number of such individuals requiring colon bacillus vaccine for complete relief of symptoms. In the second place, in the remaining group of patients who do need colon bacillus vaccine for complete relief, in addition to sodium ricinoleate and the comprehensive program, the occurrence of occasional, disagreeable, temporary reactions to B. coli vaccine has been eliminated largely by the refinements in the method of its administration outlined below.

SODIUM RICINOLEATE THERAPY

As emphasized above, sodium ricinoleate has proven to be of great aid in the treatment of these four related groups of cases. The new 5 grain, enteric-coated "Soricin" tablets are preferable, for several reasons, to the "Soricin" capsules formerly employed. The daily dose has been increased over that formerly suggested, and varies between three and six "Soricin" tablets each day. Some patients do obtain complete relief of symptoms from 1 tablet t.i.d.a.c. Others obtain only partial relief of symptoms from this dose, but secure complete relief promptly when the dose is doubled to 2 tablets t.i.d.a.c. Only very occasional patients develop slight, transient, intestinal "uneasiness" from 6 tablets per day. It is recommended that the routine dose be 6 tablets per day, as advised by Schiff (2). In the milder cases, this dose can be reduced to 3 tablets a day after several weeks. In the moderate and severe cases, the larger dose of 6 tablets per day should be maintained. If one wishes to obtain therapeutic results from "Soricin" which persist after the "Soricin" is discontinued, it is important to continue its administration for a period of four to six months—or occasionally longer. Only good effects from this practice have been noted. Sodium ricinoleate should be used almost routinely in the above related groups of cases.

COMBINED USE OF SODIUM RICINOLEATE AND B. COLI VACCINE

In obstinate cases, the best therapeutic results are obtained by the addition of colon bacillus vaccine therapy to "Soricin" therapy. In those occasional cases, within the above four groups, in which a combination of these two therapeutic agents has not re-

*From the Gastro-Intestinal Division of the Medical Department, Henry Ford Hospital.
Submitted February 28, 1937.

lieved the symptoms, one should suspect either the persistence of an important, uncontrolled, nervous tension factor, or else an early, undiagnosed organic basis for the apparently functional symptoms.

REFINEMENTS IN ADMINISTRATION OF B. COLI VACCINE

Further important refinements in the method of administration of B. coli vaccine have been developed. These improvements have resulted in an almost entire elimination of the temporary but disagreeable reactions which formerly followed colon bacillus vaccine injections in certain individuals with low tolerance.

SKIN TESTS

The first refinement has consisted in omitting the former practice of doing a preliminary skin test with concentrated, unaltered colon bacillus vaccine, before starting the therapeutic course of injections. Formerly, when one immediately gave a skin test with a one billion, or a .200 million concentration of vaccine, there were occasional cases in which there was a disagreeable temporary reaction. Such reactions do not occur if one starts with an initial, more dilute, therapeutic dose of detoxified vaccine. Moreover, as noted in the previous publication, 99% of all patients presenting the four types of conditions referred to above exhibited a positive skin reaction with a one billion concentration of colon bacillus vaccine. Therefore, a preliminary skin test with a concentrated vaccine is no longer considered necessary nor indicated.

INITIAL DOSE OF VACCINE

The second refinement has involved the reduction of the initial therapeutic dose of vaccine from 2 minims of a 50 million or 250 million concentration to 2 minims of a 5 million concentration. By this change of proceedure, one almost completely eliminates the former disagreeable, temporary reactions, which occurred occasionally with the larger initial dose. It is true that, in case patients have an initial tolerance for the higher concentrations of colon bacillus vaccine, the prompt and dramatic symptomatic relief often seen in such cases will be postponed if one starts with the more dilute vaccine. It is also true that, when starting with the 5 million dilution, several more injections are added to the usual total course. Nevertheless, it is felt that the advantage of almost eliminating the disagreeable reactions, in the occasional patients with minimal tolerance, more than justifies this reduction in the initial dose.

CRITERIA FOR DETERMINING SUBSEQUENT DOSES OF VACCINE, AND METHOD OF RECORDING DATA

The third refinement has consisted in increasing subsequent doses of vaccine more gradually. As emphasized and more fully elaborated in the earlier publication, each subsequent increase of dose, after the initial injection, should be determined by the patient's response to the last injection, and should be individualized. Two items of information should be obtained from the patient just prior to each injection, as a necessary basis for determining the size of each successive dose, viz., (1), whether any temporarily disagreeable reaction or symptoms occurred within 3-24 hours after the last injection, e.g., fatigue, malaise, headache, generalized muscle-aching, transient joint pains, or slight aggravation of the symptoms for the relief of which colon bacillus vaccine has been given; and, (2), whether the patient noted improvement or disappearance of the symptoms, following the dose last administered. If any transient reaction occurred, its character and degree should be noted. The information relative to improvement and reaction, whether positive or negative, following the last injection, should be recorded in separate columns, following columns marked off for the date and dose of each vaccine injection, upon a "vaccine memo sheet." This information should be kept as a permanent record, and the data recorded each time the patient is seen for vaccine injections. For, such data are invaluable in determining the optimum subsequent dose. Only by thus individualizing each dose can disagreeable reactions be avoided.

A slight, transient reaction, lasting only a few hours, and consisting usually of slight fatigue or malaise, is not a contra-indication to a moderate increase of dose at the time of the next injection. Reaction symptoms will be noted only occasionally with the method now employed for increasing dosage; and usually only the improvement or disappearance of symptoms will be observed. On the other hand, if reaction symptoms after any injection are pronounced, or if they persist several days, they not only contra-indicate any increase of dose at the next injection, but definitely indicate a decrease of dose, as compared with the last injection. Even more important than this, such symptoms also indicate that the time of administering the next dose should be postponed until the patient has fully recovered from any reaction. In the rare case in which a certain dose of vaccine temporarily aggravates the symptoms for the relief of which the vaccine is given, a definite and appreciable overdose has been given, viz., a dose in excess of the tolerance of this patient at the time of this injection.

It must be emphasized that B. coli vaccine, in large doses, is much more prone to produce disagreeable reactions than the vaccines of the pyogenic bacteria, for example. If one keeps this fact in mind, and starts with appreciably smaller doses of B. coli vaccine, such reactions usually will be avoided. On the other hand, it is equally important, in the case of those patients who have shown good tolerance for the smaller and medium-sized doses of B. coli vaccine, to gradually but steadily increase the dose to a reasonable maximum (tolerated) dose, if the best and most lasting therapeutic result is to be obtained. Patients who tolerate the larger doses usually obtain the best therapeutic results.

Until one has had experience with this type of vaccine therapy, the maximum dose of B. coli vaccine which may be used safely should not exceed 15 minims of a 250 million concentration. There are occasional patients with an unusually high tolerance who will benefit by more lasting results from the use of a 1 billion concentration. However, it is never advisable, in the opinion of the authors, to increase the dose beyond 8 minims of a 1 billion concentration; and the cases for these larger doses must be selected with care.

AVERAGE RATE OF INCREASE OF DOSE, AND METHOD OF VACCINE ADMINISTRATION

Although no sterotyped schedule of increase of dose should be followed, for the reasons specified above, the

following plan represents about the optimum rate for a patient with average tolerance for B. coli vaccine. Such a schedule is as follows, viz., 2 minims of a 5 million concentration intradermally, 6 minims of the 5 million concentration intramuscularly, 2 minims of a 50 million concentration intradermally, 6 minims of the same concentration intramuscularly, 2 minims of a 250 million preparation intradermally, and then 4 minims, 6 minims, 8 minims, 10 minims, and 12 minims intramuscularly of the 250 million concentration. Some patients do not tolerate this maximum dose. Others tolerate and should receive more. The above average course totals 10 injections. In occasional individuals, it may be necessary to reduce, rather than increase, the second dose, because of poor individual tolerance. Such patients usually do not benefit as much from the vaccine as those who tolerate it well.

The small doses of 2 minims of increasing concentrations, in the early part of the course, are best given intradermally as "desensitizing" doses. The doses of larger volume should be given intramuscularly and slowly into the deltoid or thigh muscles. One should not inject this type of vaccine either subcutaneously or intravenously. The possibility of unintentional intravenous injection can be avoided by pulling very gently upon the plunger of the syringe after introducing the needle into the muscle. After the intramuscular injections, massage at the site of injection tends to reduce subsequent local soreness—especially with the larger doses.

OPTIMUM INTERVAL BETWEEN VACCINE INJECTIONS, AND DURATION OF VACCINE THERAPY

The average optimum interval between successive vaccine injections is about 4 days, as recommended in the previous publication. If any appreciable reaction should occur after any injection, the interval before the patient receives another injection should be lengthened to 7 days, or more. In such an instance, the patient should have at least 2 really "good days," with complete absence of the reaction symptoms, before receiving the next injection. If one is giving unusually small doses, e.g., at the beginning of a course of treatment, and the patient is much improved for 1 or 2 days after the injection, with return of symptoms on the second or third day, the interval between injections should be shortened to 2 days, or the dose should be increased more rapidly. In fact, when giving very small doses, e.g., when using a 50 thousand dilution, the regular administration of the vaccine every 2 days, instead of every 4 days, is usually tolerated and produces more rapid results. If tolerated, the results are likely also to be more effective. Occasional patients tolerate these small injections every day.

Inasmuch as the main limitation of any type of vaccine therapy resides in the fact that its effect does not persist indefinitely, it is often advisable to continue one injection a month for the better part of a year, after completing the regular course of about ten injections. This is especially true in obstinate cases, not relieved by other types of therapy, that have obtained particularly gratifying results from B. coli vaccine. In such instances, the subsequent monthly dose should be maintained at a level of 50% to 100% of the last, maximum dose tolerated during the regular course of injections. A recurrence of symptoms can almost always be prevented in this manner. Such a plan avoids the necessity for a second complete or intensive course of vaccine therapy 4-6 months after the first course, when symptoms return in some cases. Occasional obstinate cases have been noted, whose symptoms have started to return in mild form as early as 3 weeks after the regular course of vaccine therapy. Such patients usually have chosen to come in for a vaccine injection every 3 weeks, instead of waiting for a longer interval to expire. In this manner, they are able to remain essentially symptom-free. On the other hand, in other patients, a single course of 10 vaccine injections, without any subsequent injections, has seemed to break a vicious circle, and the patients have remained symptom-free indefinitely. As yet, no method has been evolved to prognosticate, in the individual case, which patients will obtain relief for a long time, and which only temporary relief, following the first course of vaccine therapy.

DILUTIONS OF VACCINE NEEDED

The five following concentrations of detoxified colon bacillus vaccine are needed, as a minimum, to carry out the idea of a gradual increase of the dose for individuals with different tolerance, viz., bottles of 50 thousand, 500 thousand, 5 million, 50 million, and 250 million organisms per c.c. respectively. (In occasional cases, one will need a 5 thousand or a 1 billion concentration). With such an assortment of concentrations, it is possible early in the course of treatment to individualize the dose to the tolerance of each patient and to increase the dose as gradually or rapidly as indicated.

SUMMARY

(1) In an earlier publication, the authors presented the various indications and contra-indications for, and the limitations of, colon bacillus vaccine therapy. The therapeutic results definitely due to B. coli vaccine, in the four related groups of cases, were tabulated statistically. This evidence indicated that colon bacillus vaccine constituted a valuable therapeutic aid in a properly selected group of cases, in which supplementary aid was needed. The methods of preparation and of administration of detoxified B. coli vaccine were outlined.

(2) During the past two years, further experience with sodium ricinoleate ("Soricin"), using larger doses of 10 grains t.i.d.a.c., has demonstrated its great value in the four related groups of cases relieved by colon bacillus vaccine. The routine use of "Soricin," as one feature in the preliminary comprehensive program of therapy for these four groups of cases, has definitely reduced the number of cases requiring the addition of B. coli vaccine for relief. And yet, a definite group remain who need colon bacillus vaccine for complete and satisfactory relief.

(3) The occurrence of occasional, disagreeable, temporary reactions to colon bacillus vaccine, in patients with unusually low tolerance, has been largely eliminated by the following further refinements in the method of its administration.

(a) The first refinement has consisted in the discontinuance of doing a preliminary skin test with concentrated colon bacillus vaccine.

(b) The second refinement has involved the reduction of the former initial therapeutic dose of vaccine

of 2 minims of a 50 million or a 250 million concentration to 2 minims of a 5 million concentration.

(c) The criteria for determining the size of each, subsequent, optimum dose of vaccine have been discussed in detail. The size of each dose must be individualized to the patient. Prior to each injection, it is essential to determine, (1), whether any temporarily disagreeable reaction occurred following the last injection, and if so, its degree, type and duration, and, (2), whether definite improvement or disappearance of symptoms occurred following the last injection. These facts should be recorded upon a "vaccine sheet" in the history of the patient. The determination of the optimum dose each time is essential for the best therapeutic results.

(d) Although no stereotyped schedule of increase of dose can be followed, the schedule or rate of increase suitable for a patient with average tolerance for B. coli vaccine has been outlined in detail. The optimum route for colon bacillus vaccine injection has been discussed.

(e) The usual optimum time interval between vaccine injections and the indications for increasing or decreasing this interval have been reviewed.

(f) The various concentrations of colon bacillus vaccine, actually needed for the practical administration of this type of therapy, have been specified.

(4) The proper selection of cases for colon bacillus vaccine therapy, and the careful determination of the proper dose of vaccine at the time of each injection, constitute the two most essential requirements for successful results from B. coli vaccine therapy.

Infant Feeding---Individualized vs. Routine*

By

I. NEWTON KUGELMASS, M.D.
NEW YORK, NEW YORK

MILK constitutes the basis of infants' feedings. Proper choice of the milk suited to the particular infant is indispensable in successful infant nutrition. The great variety of milks available make such a choice difficult in the individual infant because of unnecessary empiricism in practice. More stress has been placed upon the various milks and their properties than on infants and their tolerance. Nutritional knowledge has advanced sufficiently to adapt effectively the required type of milk to the individual infant rather than the infant to the milk.

The type of milk selected requires modification, the procedure of choice depending upon the infant. The resulting formula may meet all the nutritional needs of the infant and yet be unsuited to his digestive tolerance. The theoretical goal in nutrition is the same for all infants but the methods of attaining it necessarily differs with each infant. Goal and method are not only necessary but inseparable in effective infant feeding. Thus, there can be no single formula for the universal feeding of infants. The percentage composition of cow's milk mixtures, imitating breast milk, becomes less important than the behavior in the infant's stomach. We have studied the response of various methods of feeding in terms of the infant's constitution as a more physiologic basis for determining the type of formula indicated.

PLAN OF INFANT FEEDING STUDY

Comparative studies of "standard formulae" prepared from various types of milk were made on infants during the first three months of life. The newborns on the service were maintained from birth with the hydrating solution given at two hour intervals throughout the twenty-four hour cycle and put on the formula under study on the second day of life. An effort was made in each case to have the infant nurse and the breast-fed infants were used as controls. Despite the willingness of most mothers to nurse their babies and our insistence in favor of breast feeding, less infants were nursed than is considered good practice. Although theoretically tuberculosis in the mother is the only contraindication to nursing, actually we have found severe postpartum disturbances affecting the mother physically and tempermentally to an extent that made nursing very trying. Breast pumps were tolerated for short periods and manual stripping was rejected by many mothers. Whatever the maternal condition the baby was weaned if the quantity of breast milk was less than an average of two ounces per feeding after the first fortnight.

Weaning during the newborn period was instituted for very definite indications and not for the purpose of these studies. Many of the infants included in the data nursed for a number of days during which time the intake of the special formula was relatively small. But during the baby's stay in the nursery the intake of the milk mixture was gradually increased until the formula under study comprised the total day's feeding. The infants' progress was under the supervision of research dietetians, Misses Cummings and McMahon and the technical data under Miss Pugsley, all devoting full time to these nutritional studies.

Over fifty well newborns were observed serially on each formula—fresh, powdered, evaporated and acid milks with breast milk as the control. Careful records were made of the physical status and functional response to the particular feeding. This was continued at home after the babies were discharged from the nursery and observed subsequently at weekly inter-

thus insuring constancy of product and of cooperation. Only normal well infants were included in this series. It is the first three months of the feeding progress of these infants that concerns this report.

ROUTINE FEEDING OF "STANDARD" FORMULAE IN WELL INFANTS

I. *Control Series.* Fifty-five normal infants were maintained exclusively on breast milk for three months. The breast feeding was started five hours after birth in newborns with a birth-weight over six pounds. Although five of these newborns had difficult deliveries they showed no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange jucie was first given half strength and gradually increased so that two ounces were given by the end of the first month. The 10 D cod liver oil was given five drops a day increasing it gradually until each infant received one teaspoonful a day. The average volume intake was 3.8 ounces per feeding during the first month, subsequent amounts not being determined. Indeed it was difficult to obtain a sufficient number of weighings during the first month to estimate the average volume intake, the accuracy is therefore indetermine for comparison with the equivalent values for artificial feedings. The average volume intake consumed during the twenty-four hour cycle was accordingly 22 ounces. The average caloric intake was about 56 calories per pound per day. The average gain in weight was 6.9 ounces per week and the average gain in height one inch per month. The average number of stools was 2.5 per day. Three of the infants developed transient upper respiratory infections; four had alimentary disturbances, i.e., one vomited, one had colic and two developed diarrhea.

Series II. Whole Milk Formula. Fifty-four normal infants were maintained on a whole milk mixture for three months. It consisted of boiled whole milk with 10% added carbohydrate. The formula was started the second day of life in well newborns with a birth weight over six pounds. Although seven of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod liver oil was offered five drops a day increasing it gradually until the infant received one teaspoonful a day. The formula was made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed by an infant was 4.0 ounces per feeding during the first month, 5.2 during the second and 6.0 during the third month, the average volume for the total day's feeding being 24, 26 and 30 ounces respectively. The average caloric intake was about 60 calories per pound per day. The average gain in weight was 6.0 ounces per week and the gain in height was 1 inch per month. The average number of stools was 3.3 per day. There were three cases of upper respiratory infection, one furunculosis and one pyelitis. But thirteen infants showed other disturbances i.e., three vomited, three had colic, one had diarrhea, four were severely constipated, one developed eczema and one had pyloric stenosis.

The distribution of alimentary upsets was not uniform at each age level, the greatest proportion being during the first month and the least during the third month: 36% during the first month, 24% during the second and 11% during the third month with an average of 24% for the entire period. Several infants with limited digestive capacities were eliminated from this study during the first month. The most striking feature was the correlation between alimentary tolerance and body build. About 80%

who showed digestive disturbances were of the lateral type. Apparently the majority of infants of linear body build are able to take undiluted boiled whole milk in amounts adequate to satisfy the appetite without revealing intestinal disturbances.

Series III. Diluted Milk Formula. Fifty-nine normal infants were maintained on a diluted milk formula for three months. It consisted of boiled half-strength milk with 10% added carbohydrate. The formula was started the second day of life in well newborns with a birth weight over six pounds. Although three of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod liver oil was offered five drops a day increasing it gradually until the infant received one teaspoonful a day. The formula was made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed per infant was 4.2 ounces per feeding during the first month, 5.4 during the second and 6.3 during the third month, the average volume for the total day's feeding being 25, 27 and 32 ounces respectively. The average caloric intake was about 52 calories per pound per day. The average gain in weight was 5.9 ounces per week and the average pain in height was one inch per month. The average number of stools was 2.5 per day. There were three cases of upper respiratory infection, six cases of alimentary disturbances, i.e., three vomited, two developed colic and one had diarrhea. The distribution of alimentary upsets was not uniform but in the opposite sense of the group on whole milk formulae. There appeared somewhat more disturbances during the second and third month than during the first. Apparently dilution does not spare infants intestinal disturbances after the first month.

Series IV. Evaporated Milk Formula. Fifty-eight normal infants were maintained on an evaporated milk formula for three months. It consisted of evaporated milk, one to two dilution, with 10% added carbohydrate. The formula was started the second day of life in well newborns with a birth weight over six pounds. Although six of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod liver oil was offered five drops a day increasing it gradually until the infant received one teaspoonful a day. The formula was made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed per infant was 4.5 ounces per feeding during the first month, 5.0 during the second and 6.3 during the third month, the average volume for the total day's feeding being 25, 25, and 30 ounces respectively. The average caloric intake was about 66 calories per pound per day. The average gain in weight was 7.1 ounces per week and the average gain in height was one inch per month. The average number of stools was 2.6 per day. There were four cases of upper respiratory infection. Five developed alimentary disturbances, i.e., two vomited, one had colic, one diarrhea and one vomited associated with asthma.

Series V. Powdered Milk Formula. Sixty normal infants were maintained on a powdered milk formula for three months. It consisted of powdered milk, one tablespoonful to two ounces of water, with 10% added carbohydrate. The formula was started the second day of life in well newborns with a birth weight over six pounds. Although five of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod liver was offered five drops a day increasing it gradually until the infant received one teaspoonful a day. The formula was made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed per infant was 4.1 ounces per feeding during the first month, 5.1 during the second and 5.9 during the third month, the average volume for the total day's feeding being 24, 26, 29 ounces respectively. The average caloric intake was about 60 calories per pound per day. The average gain in weight was 6.4 ounces per week and the average gain in height was one inch per month. The average number of stools was 2.4 per day. There were five cases of upper respiratory infection including one with otitis media. Five developed alimentary disturbances, i.e., two vomited, one had colic, three developed diarrhea, one of which was secondary to an upper respiratory infection.

Series VI. Acid Milk Formula. Fifty-six normal infants were maintained on powdered lactic acid milk formula for three months. It consisted of one tablespoonful of the powder to two ounces of water, with 10% added carbohydrate. The formula was started the second day of life in well newborns with a birth weight over six pounds. Although seven of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod iver oil was offered five drops a day increasing it gradually until the infant received one teaspoonful a day. The formula was made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed by each infant was 3.8 ounces per feeding during the first month, 5.3 during the second and 6.2 during the third month, the average volume for the total day's feeding being 22, 26, 31 ounces per pound per day. The acid feedings were taken with more avidity after the first month. The average caloric intake was about 67 calories per pound per day. The average gain in weight was 7.1 ounces per week and the average gain in height was 1 inch per month. The average number of stools was 2.7 per day. There were three cases of upper respiratory infection. Five infants developed alimentary disturbances, i.e., one vomited, two had colic, two diarrhea and the feedings were reduced.

INDIVIDUALIZED FEEDING OF "STANDARD" FORMULAE IN WELL INFANTS

Every type of formula tested was effective routinely in over 80% of the infants studied. But in each group there were always a number of non-conformists. The particular formula was not adapted to them and they reacted with alimentary offense. Even mother's milk yielded its quota of digestive intolerance. The difficulty is with the infant in each group and not with any of the formulae tested. It appears improbable that any one type of feeding will ever be universally applicable to all infants.

The five series of routine formula feedings separ-

ated the normal infants from those with latent constitutional disorders. And even among the large group of normal infants in each series there were differences in the relative tolerance for milk as the first "solid" food. The range of digestive tolerance is so wide in most infants that no abnormal responses are manifest clinically with modified milk mixtures. But in infants with latent constitutional disorders — developmental, allergic, neuropathic — there is either a low digestive capacity for any food or a diminished tolerance for cow's milk, frequently below maintenance requirement. Not all these infants rebel against "standard" formulae because the infant's functional deviations may be slow in becoming manifest.

But the constitutional stigmata persists although not always poignantly. The routine feedings unsuited to these infants may tide them over the first months of difficult adjustment but subsequently contribute to the precipitation of their constitutional disease. What may develop will develop more violently if irritated by inappropriate feedings from birth. The feeding of routine formulae to well infants from birth ignores the prevalence of latent constitutional disturbances. Many of these can be recognized early and appropriate formula adapted to their more limited digestive capacities.

We attempted to distinguish normal from diathetic newborn to determine the type of milk indicated for each infant individually. Infants with overt disturbances were excluded from this study. Of the forty-five infants with diathesis, 65% were allergic, 30% neuropathic and 5% developmental in origin. The infants that developed allergic manifestations showed enough suggestion of latent allergy to warrant early adaptation of the formula. The most helpful sign was an erythematous linear fold in the post-auricular region or beneath the lobe of the ear, more striking beneath the left than the right ear. In addition the usual premonitory expressions of allergy such as a hairless scaly scalp and desquamated dry skin were helpful. When these manifestations in the newborn were corroborated by an allergic history in either parent the infant was considered a problem in latent allergy. Neuropathic infants were recognized by hypertonic manifestations during the first days of life. There was predominance of the flexor muscles with generalized and continued spasticity, restlessness, sleeplessness and irritability. Infants with latent developmental disorders were too varied to permit of any single procedure to be of value for early diagnosis.

Series VII. Individualized Formulae. Fifty normal infants were maintained on individualized formulae for three months. The type of feeding selected was in accordance with the indications of the individual infant. Long lean infants were given 75 calories per pound of body weight per day and lateral infants were given 60 calories. The former were fed concentrated whole milk mixtures, three to one dilution with 10% added carbohydrate, and the later diluted milk mixtures, one to one dilution with the same amount of added carbohydrate. Infants with latent allergy were given evaporated milk, one to two dilution with 10% added carbohydrate, with a caloric intake depending upon their body build. Infants with hypertonia were maintained on acid milk, one tablespoonful to two ounces of water with 10% added carbohydrate.

The formulae were started the second day of life in well newborns with a birth weight over six pounds. Although four of the group studied had difficult deliveries there were no post-natal manifestations. Orange juice and cod liver oil were introduced the third week. The orange juice was first given half strength and increased gradually so that two ounces were given by the end of the first month. The 10 D cod liver oil was offered five drops a day increasing

Milks indicated for infants

Infant Types (392 Babies)		
Linear (20%)	Medial (25%)	Lateral (55%)
Breast Milk	Breast Milk	Breast Milk
Cow's Milk (3:1)	Cow's Milk (2:1)	Cow's Milk (1:1)
Evaporated Milk (1:1)	Evaporated Milk (1:1½)	Evaporated Milk (1:2)
Powdered Milk (1:7)	Powdered Milk (1:8)	Powdered Milk (1:10)
Infant Diatheses (45 Cases)		
Allergic (65%)	Neuropathic (30%)	Developmental (5%)

Vegetable Milk		

it gradually until the infant received one teaspoonful a day. The formulae were made up for twenty-four hours and divided into six feedings given at four hour intervals during the first month and subsequently into five feedings. The amount offered at each feeding was slightly above that usually taken by infants at each age level.

The average volume consumed per infant was 4.4 ounces per feeding during the first month, 5.5 during the second and 6.5 during the third month, the average volume for the total day's feedings being 26, 27 and 30 respectively. The average caloric intake was about 70 calories per pound per day. The average gain in weight was 7.3 ounces per week and the average gain in height one inch per month. The average number of stools was 2.6 per day. There were four cases of mild upper respiratory infection and one infant vomited.

EVALUATION OF RESULTS WITH ROUTINE AND INDIVIDUALIZED FEEDING

I. *Comparative Intake of Formulae.* The ingestion of various types of formulae was relatively uniform in amount for each group studied. During the first month the infants on breast milk took such varied amounts at each feeding that the average volume intake is of little significance in comparison with artificial feeding. Apparently the effort exerted in nursing is more of a factor than appetite in determining the volume intake at a feeding. The placid rôle of infants on artificial feeding accounts for the relatively uniform intake on the various types of prescribed formulae.

Infants took less of the acid formula during the first month but once they became adapted to it they took more of that formula than of the others. During the entire period of study infants took more of the processed milk formulae than of the whole milk formula. And those on individualized feedings consumed more per feeding as well as for the twenty-four hour cycle. This is partly due to the fact that more infants were

included in the series who have taken feedings steadily without alimentary upsets. The caloric intake per pound of body weight per twenty-four hours was greater on the more concentrated feedings, the least being with the diluted milk mixtures and the most with the acid and individualized formulae.

II. *Comparative Tolerance of Formulae.* Food tolerance is estimated clinically without quantitative criteria. It is difficult to make comparative estimates of the relative degrees of tolerance for the formulae tested. Quantitatively an infant's tolerance for a food represents the ratio of the maximum amount of the food he can metabolize without resultant disturbances by the maximum amount of that food metabolized by a normal infant of the same age group. We must necessarily deal with maximum rather than with optimum intake in the consideration of tolerance because we do not know what the optimum of any food is quantitatively for any infant. But we do know that there is a wide range between the minimum and the maximum and that any attempt to exceed the maximum produced a variety of disturbances essentially alimentary in nature. We are, therefore, led to the evaluation of tolerance of various formulae by a negative qualitative method of procedure. Those formulae consumed in the required amounts were considered well tolerated if they produced no untoward symptoms while those which produced digestive disturbances apparently exceeded the digestive capacities of the infants and were considered poorly tolerated.

All types of formula were well tolerated, excepting the whole milk mixture during the first month. There were the least number of digestive upsets on the individualized formulae and on the breast feeding throughout the feeding period studied. There were less digestive disturbances on breast feeding than on fresh milk formulae. Only significant symptoms of digestive disturbances were included in this evaluation of tolerance for much of the minor symptomatology was more an expression of mismanagement than of misfeeding. However, a feature that is frequently neglected in relation to food tolerance during the first three months of life is the increased nervous tone of infants in both breast and bottle feeding. It is usually alleviated by transient modification of the feeding quantitatively or qualitatively rather than by resorting to sedatives. The number and quality of the stools were not considered diagnostic of the normal range of alimentary function although frequency or abnormal character of stools were deemed pathognomonic of gastro-intestinal disturbance.

A striking feature of the two groups on the fresh milk mixtures was the relation between milk tolerance and body build in well infants. During the first two months there was a relatively great preponderance of digestive disturbances amongst those infants who were maintained on the whole milk formulae. Eighty per cent of those infants were of the lateral body build. Most of the linear type infants tolerated whole milk mixtures without any disturbances. Apart from food tolerance the caloric requirement from body surface considerations indicates that the linear infants require about seventy calories per pound of body weight while the lateral infants require about fifty-five calories. This difference in energy requirement appears to parallel their differences in tolerance. It is curious that the high gastric acidity during the first week of life should not increase the digestive capacities of all infants sufficiently to enable them to tolerate whole milk formulae. But after the second month the percentage of disturbances was parallel to those in the other groups.

A significant number of digestive upsets occurred in the group maintained on breast feeding. Excluding disturbances resulting from faulty technique in nursing those that persisted were of the same order of magnitude as in the infants on artificial feeding. The time-honored procedure of analyzing breast milk chemically for the gross constituents is considered irrelevant. Even analysis of the minutae is unnecessary because deficiency disease has a long latent period before inducing disturbances. The difficulty, we believe, is usually with the infant constitutionally and not with the milk chemically. But weaning was not deemed necessary until supplementary procedures failed to allay the disturbance.

The formulae prepared from processed milk were the best tolerated. Off hand, these would appear the most logical for routine use in infant feeding if nursing is impossible but such an approach defeats the very purpose of infant nutrition. The types of feeding that meets with the digestive capacities of the infants is indicated rather than that which least utilizes digestive mechanisms. It is the newborn's task to adapt to "foreign" foods—a biologic and therefore a physical necessity. Ability to digest a food is gained by ingesting the food in gradually increasing amounts. The more work the digestive mechanism is made to perform the greater the alimentary efficiency. The indications in normal infant feeding are fresh milk mixtures for the infants that can tolerate them and processed milk mixtures for those with diminished digestive capacities.

III. *Comparative Nutritional Status.* The adequacy of each type of feeding is best determined by the character and rate of growth of the infants of each group. But again growth evaluation is clinical rather than quantitative because we have no absolute standards of the composites of growth for each age level. Average weights and measurements of infants cannot be taken as guides for the developmental progress of an individual infant for the average infant is nonexistent. Developmental progress of an infant can best be evaluated in terms of himself as a standard and the increments of growth accruing at periodic intervals as the individual criteria of satisfactory achievement. These are based more upon clinical judgment than upon mere measurement. They include a variety of external manifestations of wellbeing such as type of facies, color of mucous membranes, condition of skin, quality of subcutaneous tissues, tissue turgor, muscle tone and skeletal characteristics. Even these properties of an infant are, during the first weeks of life, more an expression of his heredity and constitution than of the type of feeding instituted.

Each group of infants thrived on the various formulae as on the breast feeding. The greatest gain in weight was in those on individualized feeding and the least on the diluted milk formulae. The infants on breast feeding and on the processed milk formulae gained more rapidly than those on the fresh milk mixtures. The more concentrated the formulae the more rapid the weekly gain in weight. In no group did this necessarily represent mere accumulation of adipose

tissue. Despite the high gains in weight there were no manifestations of overfeeding. In fact we have observed no absolute relation between the high gains in weight and quantities of formulae ingested. This applies to both the breast and artificially fed infants. Large lateral infants, for example, with birth weights of about eight pounds made more satisfactory gains on twenty ounces of a formula per twenty-four hours than did the long lean infants with a birth weight of about seven pounds on an intake of twenty-five ounces. But on all types of feedings the gain in height was practically the same at least for the first three months. In each group the incidence of infection was about the same, acquired in most infants from adult contacts.

CONCLUSIONS

1. Comparative studies of "standard" formulae were made on 337 infants during the first three months of life with 55 breast fed infants as controls. The formulae consisted of whole milk, half diluted milk, evaporated milk (1 : 1), powdered whole milk (1 tablespoonful to 2 ounces of water), powdered lactic acid milk (1 tablespoonful to 2 ounces of water), each reinforced with 10% added carbohydrate. Each group maintained on a routine formula was compared with a group of 50 infants given individualized formulae.

2. The infants consumed more of the processed milk formulae than of the fresh milk formulae and the maximum was on individualized feedings throughout the period of study. The least number of digestive disturbances was observed on breast feeding and on individualized formulae.

3. The linear type infant required about 70 calories per pound of body weight and tolerated concentrated milk mixtures while the lateral type infant required about 55 calories per pound of body weight and tolerated diluted milk mixtures better.

4. Maximum gains in weight were observed in infants on individualized feeding and the minimum on diluted milk formulae. Infants on breast feedings and on processed milk feedings gained more rapidly than those on the fresh milk mixtures. The gains in height were the same on all types of feeding during the first three months. The incidence of infection was about the same for each group of infants studied.

5. Standard routine formulae were effective in over 80% of the infants studied. The residual nonconformists represented infants with latent constitutional disorders—organic, allergic and neuropathic—with either lowered digestive capacities or diminished tolerance. The early recognition of these types displaced routine by individualized feeding. This group showed the highest percentage of successful infant feeding.

A Case of Trichomonas Hominis Infestation

By

HORACE W. SOPER, M.D., F.A.C.P.*
ST. LOUIS, MISSOURI

KOFOID (1) points out the difference in the relative importance of the parasitic protozoa, such as the intestinal flagellates, and the hematozoa, *e.g.* trypanosomiasis, leishmaniasis, malaria, etc. The latter group is more catastrophic in its relations to the host than are the intestinal flagelloses. Kofoid believes that the flagellate parasites of the intestines may have more generalized capabilities of tissue invasion than has been hitherto suspected or detected. He states that there is abundant clinical evidence to the effect that they may be harmful when there is a disturbance of the normal bowel condition in the host due to exposure or infection as a result of which the resistance of the host is impaired.

Hinklemann (2) reports that 5 c.c. of blood from a human case of diarrhea and intermittent fever, mixed with distilled water and centrifuged, show all the features of Trichomonas intestinalis.

Ratz (3) found Trichomonas in the liver of pigeons.

The appearance of Trichomonas in pleural transudates and exudates in man as well as the cancers, ulcers, lesions of the mouth, jaw, tonsils, esophagus and stomach also occasionally in liver abscesses is suggestive that it may have tissue invasive powers.

The older German gastro-enterologists believed the flagellates to be non-pathogenic, occurring in the feces in most of the chronic diarrheas.

My experience has been limited to those more commonly occurring in my practice such as Trichomonas, Chilomastix mesnili, Giardia enterica, Cercomonas and Balantidium coli.

Close study of the feces of infected individuals give evidence of a low grade chronic entero-colitis. The treatment of all the flagellates that I have mentioned with *the exception of the Giardia enterica* is extremely simple. I employ stovarsol 0.25 gram tablet three times a day before meals for a period of three days. I have employed the follow-up method in a large number of cases and I have never known this drug to fail to completely destroy the organisms. The endamoeba coli is also quickly eradicated by this method of treatment.

There is no question about the pathogenicity of Giardia enterica. Quite a number of chronic duodenal ulcer patients show Giardia infestation. In my hands patients with Giardia infestation usually show a recurrence about four weeks after the treatment that was used.

Jelks (4) recommends transduodenal irrigations of a solution of neo-arsphenamine.

Barrow (5) and many others employ stovarsol or carbarsone.

Smithies (6) recommends five to ten grains of calomel followed by a saline. This dosage may be repeated in one week's time. The patient is given thymol

*From the Soper-Mills Clinic.
Submitted January 25, 1937.

after a "fat-free" diet and in obstinate cases small doses of neo-arsphenamine intravenously.

Recently I have employed a modification of the Smithies method. I give the large dose, grain 5 to 10, of calomel at bedtime followed in the morning by a mixture of magnesium and sodium sulphate. The following day 0.45 of neo-arsphenamine is given intravenously. The drug is injected very slowly and carefully to avoid any untoward sensitization which might occur in the patient. Two days later a second dose of 0.45 neo-arsphenamine is given. The follow-up of the ten patients whom I have treated show as yet no recurrence of the organisms. The *rationale* of this method of treatment is probably the large dose of intravenous arsphenamine administered while protozoa are weakened by the calomel and saline.

CASE REPORT

Recently I came across a very unusual case of infestation by Trichimonas hominis:

Male, white, aged 52. Salesmanager. Height 6 foot, 1 inch. Weight 255 pounds. Came under Dr. Hanford Phillips care August 17, 1936. His chief complaint was dull pain in the sacro-iliac and lower lumbar region. One week ago he had had prostatic massage and a urethral sound was passed which was followed by chill and high fever. He developed what appeared to be an acute cystitis. Staphylococcus was grown on the culture. Within a few days he developed an eruption of purpura hemorrhagica involving the lower extremities and forearms. Finally on September 8, he had an attack of severe pain in the upper abdomen with vomiting and fever. He was sent to the Missouri Baptist Hospital on September 11. Blood analysis as follows: Red blood cells 4,750,000, Leucocytes 20,800. Differential: Eosinophiles 1, Stabkernige 24, Segmented 53, Lymphocytes 17, Monocytes 5, Blood playelet count—290,000. Stool culture was negative for typhoid and the Bargen diplococcus.

He continued to have fever and needed sedatives for the pain. The feces analysis on September 14 showed strong positive occult blood reaction.

X-ray examination by Dr. Arthur C. Echternacht revealed the following findings: "Fluoroscopic examination of the chest preceding the ingestion of an opaque meal reveals no gross pathological changes. The stomach, which was of the "steer-horn" type, filled readily and a normal gastric tone and peristalsis was observed. There was no evidence of an intrinsic gastric or duodenal lesion. Three hour film shows only a trace of barium remaining in the stomach. The head of the barium meal had reached the cecum. There was a large quantity of barium remaining in the upper portion of the small intestinal tract which shows the calibre to be unusually large, also the outline of the lumen of the small bowel crossing the spine which suggests the possibility of a neoplasm. However, that may be due to intrinsic pressure. The six hour film shows the stomach to be completely empty of the barium meal with a large portion of the meal remaining in the upper portion of the small intestinal tract at approximately the same location as was seen on the three hour film. This portion of the small bowel still shows an unusual dilatation also an irregularity of the small bowel as it crosses the spine as was seen on the three hour film. The retention of the barium in the same location of the small bowel suggests the possibility of some obstruction distal to this point. The head of the barium column had reached the hepatic flexure of the colon. Twenty-four hour fluoroscopic examination reveals the barium to be in the cecum, ascending, and transverse colon, also sigmoid and rectum. Fluoroscopic study of the colon during the administration of a barium enema reveals the shadow casting solution to pass readily through the colon from the rectum to the cecum.

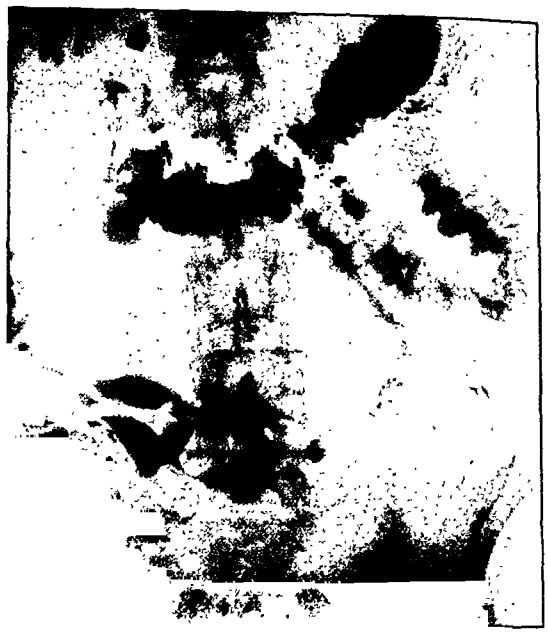

Fig. 1. Three hour film. Stomach empty. Dilatation of the duodenum and jejunum and irregularity of the jejunum at its junction with the ileum. N.B. The 6 hour film was almost identical with this one.

There were no irregularities noted anywhere along the colon. Conclusions—G. I. X-ray examination suggests the possibility of a partial obstruction in the upper portion of the small intestinal tract, possibly from two to four feet from the pylorus." I present one of the films. (Fig. 1).

On September 22, I was called in consultation with Drs. Hanford Phillips and John W. Hotz, and from a study of the history and review of the X-ray findings and the strong occult blood reaction in the feces, made a diagnosis of carcinoma involving the jejunum, and advised surgery. Dr. Hotz operated on September 24. His findings are as follows: "Left para-median incision-muscle retracted laterally. Abdomen opened—no free fluid. Liver was not enlarged, edges were free and smooth. Gall bladder soft and emptied freely. Foramen of Winslow showed nothing. Stomach was soft and had no abnormalities. Pancreas was smooth, normal consistency, not enlarged. Both kidneys were normal. Spleen was small, edges smooth. Colon is smooth, no masses, somewhat distended to palpation. Exploration of the small bowel reveals that from the ligament of Treitz extending down throughout the entire angle of the jejunum, the bowel was distended, thick, having a soft doughy consistency, about four times as large as the ileum. The mesentery was normal, however the entire jejunum was covered with minute blood vessels which bled into the wall of the bowel on the slightest provocation."

The question arose as to whether the condition of the jejunum was a manifestation of purpura or the staphylococcus infection in the bladder. The bladder condition readily cleared up after a course of large doses of sodium benzoate.

At this time I secured a specimen of the feces and found it to contain a large number of Trichomonas hominis. I at once administered the specific medication of stovarsol for a period of three days. Improvement was now rapid. Temperature subsided. He was able to retain his food and the occult blood disappeared from the feces. The purpura completely disappeared from the skin. X-ray films of the spine revealed the presence of an exudative arthritis involving the lumbar and sacro-iliac joints.

He was able to return to his home two weeks after the operation. He was now put on a low cholesterol diet, given two grains of dessicated thyroid once daily and twenty drops of saturated solution of sodium iodide three times a day. Both of these drugs are lipoid solvents. A sacroiliac and lumbar spine belt was prescribed.

He has made splendid response to treatment. His weight is now 220 pounds. He is active in his work, his general condition is splendid, feces are now normal in appearance and free from mucus.

In my opinion, the acute process found in the jejunum was produced by the Trichomonas hominis because it rapidly subsided after the administration of the specific drug—*stovarsol.*

Abstract by

J. ARNOLD BARGEN, M.D.†

and

ANTONIO E. MENDES FERREIRA, M.D.‡

ROCHESTER, MINNESOTA

ULCERATIVE colitis is a disease of the large bowel which has been called "idiopathic" by the old authors and "gravis" by the Germans; some authors, particularly the Americans, recently have called it "bacterial."

The disease is characterized by a series of well-defined symptoms, a typical proctoscopic picture, a tendency to recur, and a bad prognosis. The anatomopathologic changes consist of inflammation and diffuse erosion of the large intestine; the evolution is purely destructive. The small bowel is usually not involved. The large bowel may be totally or only partially involved. A sharp demarcation between the pathologic and the healthy segments of intestine practically never exists. Microscopically, the disease is conspicious by the presence of numerous ulcers in the colon. The appearance of these ulcers is variable in different portions of the colon.

In some regions of the colon the ulcers are of different diameter but are small and numerous. Histologically, the mucosa in the borders of the ulcers disappears suddenly and does not show any defensive reaction. The most intense destructive reaction is found in the submucosa; the loss of the mucosa seems to depend on a primary modification in the submucosa. The destructive process has a dissecting tendency; it slowly destroys the vascular connective tissue of the submucosa. The mucosa resists and is saved; the connective tissue of the submucosa dies because of lack of nutrition as a result of the destruction of the blood vessels. The walls of the ulcers do not show any sclerosing phenomena. The only reaction is a perivascular infiltration with lymphocytes, plasmocytes and histiocytes. Sometimes, the ulcerated regions of the colon are larger than the regions covered by mucosa. The muscle may be exposed and in some places one may see islands or strips of mucosa, which sometimes form polypoid elevations. In the sigmoid flexure and rectum, one sometimes sees extensive ulcers whose longest axes are directed longitudinally. These ulcers are different from the ones previously described, because they are not so deep and the mucosa around them is congested and bleeds easily. Histologically, the only difference is that in the ulcers in the sigmoid flexure and rectum there is greater congestion in the vessels of the submucosa and there is a more abundant exudate between the necrotic tissues of the ulcers. The necrotic tissues have a fibrinous appearance. Sometimes, the destructive process extends through the muscular layer and perforation kills the patient. The tissues around the perforation are greenish. When the muscular destruction is produced in the lower portion of the rectum (extraperitoneal) the result is an infection of the perirectal tissues and the formation of an abscess.

ETIOLOGY

The authors reviewed the etiology of ulcerative colitis. They said that the bacterium which was found by Bargen is a diplostreptococcus which is easily isolated by Rosenow's method. In fact, if one makes cultures from the intestinal ulcers, in Rosenow's fluid brain medium, and if one maintains them under conditions of proper oxygen tension or anaerobically and follows the steps advised by Bargen, and makes subcultures on agar-blood plates or makes cultures from the mesenteric lymph nodes of rabbits which previously have received inoculations, it is very rarely

that one does not find bacteria that have the cultural characteristics of the diplostreptococcus.

Happily, the Bargen technic for identification of the diplostreptococcus is simple. Bargen said the diplostreptococcus has hemolytic properties and that the hemoglobin becomes green. It seemed that the diplostreptococcus of Bargen, according to the classification of Brown, should be considered as a streptococcus mitis, variety, number 2. The streptococcus mitis is a well known bacterium that is found in many infectious processes. It frequently is found in the mucosa of the upper part of the respiratory tract of healthy persons or of patients who have subacute or chronic inflammations. To give this organism etiologic significance it is necessary to take into account the theory of elective localization propounded by Rosenow and others.

The authors studied bacteriologically twenty-five characteristic cases of ulcerative colitis and twenty-five cases which were used as controls. They found the Streptococcus mitis in 30 per cent of the cases of chronic ulcerative colitis and also in 25 per cent of the cases which were used as controls. The Streptococcus saprophyticus, which has been described by Buttiaux and Sevin as the cause of certain types of ulcerative colitis, was present in 8 per cent of the cases of chronic ulcerative colitis and in 16 per cent of the cases which served as controls. In one case the diplostreptococcus which was isolated was of the infrequent type, which is very different from the type described by Bargen. In this case the diplostreptococcus was isolated from rectal ulcers and from ulcers that later developed on the skin and mucous membrane. The ulcers of the skin and mucous membrane were very much like the ones in the rectum. The authors expressed the opinion that different kinds of streptococci can have a pathogenic action in certain phases of chronic ulcerative colitis.

The authors did a good deal of experimental work. They injected, intravenously, large numbers of bacteria into rabbits and dogs. Characteristic lesions occurred only rarely. The authors said that among the different bacteria that have been considered the cause of ulcerative colitis, streptococci are most important. When one makes bacteriologic examinations of specimens obtained from intestinal lesions, one's attention is called to the small number of bacteria found. The cultures obtained from scrapings of diseased mucosa which are made in Rosenow's medium and the subcultures which are made in the same medium always permit the isolation of a diplostreptococcus or short chains that initially have the characteristics that Bargen attributed to his diplostreptococcus of ulcerative colitis. This bacterium and most of the diplostreptococci found in ulcerative colitis often have a pathogenic action when injected into rabbits. The same bacteria isolated from healthy people usually have no pathogenic action.

The authors investigated the part the filtrable virus played in the production of chronic ulcerative colitis. They took scrapings of the intestinal mucosa of healthy persons and of the ulcers of chronic ulcerative colitis. Afterward, they made an emulsion in sterile physiologic saline solution and filtered it through a filter L.3 and injected that filtrate into the brains (0.2 c.c.) and veins (3 c.c.) of rabbits. The lesions produced by the injection of the filtrate were remarkable, and sometimes were situated in the intestine. These lesions were comparable to those produced by injection of pure cultures of the streptococci. Lesions did not develop in the animals which were used as controls. This fact suggested to them that in ulcerative colitis there exists some principle which confers pathogenic value to bacteria that ordinarily are not pathogenic.

The authors made further experiments trying to determine whether chronic ulcerative colitis was produced by a filtrable virus. They observed that the virus lost its action when cultivated in solid medium and after subcultures had been made; furthermore, they observed that when it was cultivated in the fluid medium of Rosenow, it was much more active, especially after the first transfer, but its action was complex. It produced more acute lesions because it was associated with other toxic substances which were derived from the bacteria. The virus is maintained at the expense of the live streptococci, when these are cultivated in anaerobic conditions and mainly in fluid medium. For these reasons the authors used to make injections of direct filtrates. The virus, they said, can be isolated from patients who have acute, subacute, or chronic ulcerative colitis. However, they thought that it had more pathogenic power or that it occurred in larger amounts when it was obtained from patients who had acute ulcerative colitis. In order to obtain an emulsion of the virus the patient was given an enema of 1000 c.c. of physiologic saline solution. The mucosa was cleansed with the aid of a proctoscope and the ulcers then were scraped four or five times and the material placed in 20 c.c. of sterile physiologic saline solution. The tube was shaken energetically and the emulsion was filtered through sterile filter paper. After this first filtration, the filtrate was filtered through a new, sterile, dry, porcelain filter (L.3). The filtrate was kept in an icebox at a temperature between 1° and 5° C.

After the virus was injected into animals, it was distributed throughout the body, especially in the spleen, and it always could be isolated again by maceration of one part of spleen in 10 parts of physiologic saline solution.

The virus may be administered to animals subcutaneously, intravenously, or intracerebrally. The results of the experimental disease were about the same regardless of the method of administration; however, the authors preferred the intravenous method. If the animal was a rabbit, 3 c.c. of the virus per kg. of body weight was given; if it was a guinea-pig, 1 c.c. per kg. of body weight was given, and if it was a dog, 0.5 c.c. per kg. of body weight was given. The animals which were most sensitive to the virus were the dog and rabbit; the sensitiveness of these animals was very similar. The guinea-pig was only slightly sensitive and the rat was not sensitive at all.

The authors considered the virus isolated only when they could produce the disease in a series of animals. Many animals died from intercurrent diseases. Successive passages through animals had a tendency to decrease the activity of the virus. After the virus had been passed through four or five animals, it lost its virulence, although it occasionally retained its virulence after passage through nine or ten animals. The passage from one animal to another of a different species also decreased the virulence of the virus.

It was impossible to isolate the virus in all stages

of chronic ulcerative colitis, and all of the rabbits which received injections of the virus did not become ill. Local lesions did not occur at the point of injection. Fifty-five per cent of the rabbits which received injections of filtrates became ill, and 88 per cent of those which received injections of filtrates that had been passed once through Rosenow's culture medium became ill. Of the rabbits which received injections of a virus that previously had been passed through another rabbit, 40 per cent became ill, and 33 per cent of those which received injections of a virus that previously had been passed through two rabbits became ill. After that the percentage did not decrease in the same order; on the contrary, when the virus had been passed through several animals of the same species, its virulence increased again and 70 to 80 per cent of the animals that received subsequent injections of the virus became ill. Almost all the rabbits had diarrhea and some of them passed bloody stools. They became weaker and weaker until they died.

In the digestive tract of the animals were found lesions which varied from simple congestion to deep ulceration; however, the most frequent lesions were small hemorrhages in the mucosa and submucosa. These lesions were particularly frequent in the rectum and small intestine. When animals lived more than one month, these lesions produced stenosis. Hemorrhagic and desquamative changes were occasionally seen in the stomach, liver, kidneys, suprarenal glands and nervous system. About 50 per cent of the rabbits that received injections of the virus died within ten days, and 10 per cent died between twenty and forty days after the injection.

The experimental disease of dogs was more like the chronic ulcerative colitis of man than it was of rabbits. A few days after the injection, the dogs began to show evidence of intestinal disturbances. These were ushered in by diarrhea; the stools usually contained a large amount of blood. The animals did not eat and they became more and more cachectic until they died. Some of the dogs seemed to overcome the disease, but ten or twelve days later they had a recurrence. At this time the stools usually were more profuse and contained more blood than they had at the onset. In some cases a localization in a vital organ killed the animals quickly. Often, the organs of vision were affected; this produced blindness which was total or partial and permanent or transitional. Examination of the digestive tract revealed lesions which extended from the stomach to the rectum; inflammatory regions alternated with other regions in which the mucosa appeared normal. The lymph follicles of the mucosa were enlarged and filled with bloody material. More than 80 per cent of the dogs that received injections of a virus obtained from patients who had an acute phase of chronic ulcerative colitis became ill.

The authors expressed the opinion that the resulting lesions initially originated in the blood vessels. Furthermore, they were of the opinion that the virus produced vascular lesions. The small vessels of the intestine were readily damaged. The primary reactions against the virus were probably produced by the reticulo-endothelial system, mainly by the endothelial cells of the vessels, which finally produced emboli. Then the vessels without endothelium permitted the blood to pass through into the connective tissue and peri-endothelial tissue. These hemorrhages compressed the vessels and produced obliteration. Damage to the walls of the vessels and obliteration of the vessels were the fundamental factors from which were derived all the anatomopathologic features of the experimental disease. When the lesions affected mainly the intestinal villi, there were congestion and edema of the mucosa, desquamation of the epithelium, and small hemorrhages. All these alterations in the vessels and the secondary modification that followed made the intestinal mucosa a good field for implantation of other bacteria, which frequently changed the anatomopathologic picture. The Streptococcus mitis mainly, and other species of streptococci, and several kinds of bacteria found in the lesions made conditions ideal for the development of chronic ulcerative colitis. The virus was not different in its pathogenic action from the virus of scarlatina. Like the latter virus, it produces among human beings a disease in which it is difficult to separate the action of the virus from the action of the bacteria which play an important but secondary part.

CLINICAL OBSERVATIONS

The authors expressed the opinion that the ulcers seen in the digestive tracts of patients were the result of simple secondary infection produced mainly by the Streptococcus mitis. This opinion was based on the observation of ten patients who had chronic ulcerative colitis and twenty human beings who served as controls.

In more than three-fourths of the cases the patients had a little fever, and in some acute forms of the disease the temperature reached 104° F. and occasionally it was maintained for more than two months. Sometimes, the fever was of a septic character without any apparent complication. One of the more constant symptoms observed was a slight anemia. It was marked in some acute forms and in certain chronic forms in which the preponderant symptom was bleeding. A slight leukocytosis usually was noted and there was a deviation of the leukocytes to the left but the authors never noted an increase in eosinophils, as described by Albu. The authors emphasized the value of proctoscopic examination, and said that one never can say that a patient is cured if the rectosigmoidoscopy and the roentgenograms do not prove it. Four of their patients who had acute ulcerative colitis died in less than four months, and one died in a few weeks. Some were cured, but in other cases the disease became chronic. In most of the cases of chronic ulcerative colitis the disease was chronic from the beginning and was characterized by recurrences, alternating with phases without symptoms.

The authors divided the complications of chronic ulcerative colitis into local, or intracolic, and extracolic. They referred to the former as the most frequent and reported that they comprised polyposis of the rectosigmoid, diffuse polyposis throughout all the colon, rectal stenosis, stenosis of the sigmoid colon, neoplastic degeneration, and perforation. They never noted a fatal hemorrhage in the cases which they observed.

Extracolic complications included arthritis of the wrists, shoulders, and tibiotarsal joints; perirectal abscess and multiple fistulas; nephritis; ulcerations of the skin and palate; purpura and phlebitis. In one case of acute ulcerative colitis the authors noted

splenomegaly which disappeared when the disease became chronic, and reappeared during a recurrence. In one other case the patient also had perirectal abscess, ulceration of the palate, arthritis, pseudotuberculides of the skin, and pyodermitis. Another patient had chronic ulcerative colitis, polyposis, and cancer.

Most of the patients who had perirectal abscesses were cured only by ileostomy or colostomy. Arthritis was a frequent complication, particularly in acute stages, and the authors noted that arthritis tended to occur with each recurrence. However, arthritis was usually chronic and did not respond to the administration of salicylates.

TREATMENT

The authors were skeptical of the results of treatment. Results with irrigations have been very discouraging. Mechanical cleansing with physiologic saline solution seems helpful. They reviewed the different treatments proposed. Mediocre results followed the administration of Bargen's serum and vaccines. They did not see any local improvement as a result of Rachwalsky's treatment with blood transfusions. They tried Logan's treatment, which consists of the administration of tincture of iodine, the autohemotherapy proposed by Bensaude, the administration of calcium and parathyroid extract advised by Haskell, and the Kalk treatment. The best results were obtained with the administration of reduced iron (2 to 4 gm. a day) and with the administration of opium for a long time.

They advised an adequate diet which was high in calories and vitamins, low in residue (cellulose), and easily digestible. They allowed some light alcoholic drinks with the meals.

COMMENT BY ABSTRACTORS

The results of treatment reported in this monograph differ from those obtained by the abstractors. Our experimental work would suggest that the essential lesions may be caused by the streptococcus or its toxins. The work of the authors of this monograph indicates that the damage is done by the filtrable virus in association with the streptococcus.

Causes and Treatment of Peptic Ulcer*

By

PAUL CAMPICHE, M.D.

SAN FRANCISCO, CALIFORNIA

BY the term "peptic ulcer" we refer, in this paper, to gastric or duodenal ulcer produced by the corrosive action of the acid chyme on the mucous membrane. This definition excludes ulcers resulting from arteriosclerosis, specific infections or malignant growths.

The Causes of Peptic Ulcer: Various opinions and hypotheses have been advanced as to the causes of this condition (1, 2) and a great deal of confusion prevails because one writer describes as essential factors which other authors consider purely secondary.

The subject would be made much clearer and easier to grasp, if we could classify the causes of ulcer in a simple and rational manner.

Aristotle, in his "Logic" laid down the different kinds of causes, namely: the *material,* the *formal,* the *efficient,* and the *final.* To these, various old church writers added the *occasional cause.* As really important causes, for example, in the construction of a house, we have:

I. The material (stone, marble, wood) of which the house is made—this is the *material cause.*

II. Some special event or circumstance, such as marriage, an increase of family, etc., to be commemorated—this is the *occasional cause.*

III. The plan, type or pattern of the architect giving the location, size, shape and architecture of the building—this is the *formal cause.*

IV. The energy of the workmen who actually build the place—this is the *efficient cause.*

V. The will or final motive of the owner who decides and gives the order to build—this is the *final cause.*

Modern metaphysicians have discarded this classification as being too simple and inadequate when applied to spiritual conceptions. We physicians, being chiefly concerned with terrestrial things, find that it still retains its value in helping us to distinguish physical causes so that we may have a clear idea of what we are doing and of what we are talking about.

If we examine the causes of peptic ulcer in the light of the foregoing classifications, we find the following:

I. THE MATERIAL CAUSE

This lies in the biological structure of the tissue—the gastric and duodenal mucosa—in which the ulcer originates.

Ochsner (3) and others assume that, in certain persons, there is an inherent susceptibility of the tissues, a lack of resistance to the action of the gastric chyme. What is this material defect in the mucous membrane that makes it more vulnerable in some people than in others? We do not know. This being, however, the soil on which the ulcer grows, attempts have been made to modify its composition by using subcutaneous, intravenous or intramuscular injections of various substances such as pepsine, sodium benzoate, nonspecific proteins, milk, etc., with the idea of improving the chemical structure and the resistance of the mucosa.

In 1933, Aron and Weiss (4), experimenting on dogs, found that the loss of amino-acids, by weakening the tissues, caused ulcers to appear in the stomach and in the jejunum; these ulcers, they believed, were cured

*From the Department of Surgery, University of California Medical School, San Francisco.

Submitted February 2, 1937.

or prevented by the subcutaneous injection of histidine. The Hoffmann-LaRoche firm immediately put on the market their product "Larostidine" which many people are trying at the present time.

The hypothesis advanced by Aron and Weiss fails to explain why so many people who are on a regular diet, including amino-acids, should develop ulcers. The symptomatic cures obtained by this method are mostly of the "objective" kind. Some observers are very enthusiastic; others remain skeptical about it. It will take years before the final results of this therapy can be determined, especially as regards recurrence.

Though it is interesting to see the problem attacked from the somewhat neglected angle of the "material cause," we shall have to admit with Ochsner that, for the present, the susceptibility of tissue is still an uncontrollable factor.

II. THE OCCASIONAL CAUSE

The occasional cause is represented first by small injuries to the gastric mucous membrane resulting from various agents which are either *mechanical*, such as abrasions by foreign bodies, roughage, and operative wounds, or *chemical*, for example, erosions caused by acid foods, stimulants, spices, tobacco and other irritants; secondly, by circulatory disturbances such as local anemia (anemic spots of Aschoff) (5) with vascular spasm; or congestion (small hemorrhagic spots of Virchow) (6) followed by small patches of necrosis. These changes may be caused by *physical agents* (very hot or very cold drinks), local inflammation, or distant foci of infection such as infected tonsils or apical abscess producing small bacterial emboli, the action of toxins (burns, uremia); common colds, general infections, emboli after abdominal operations, etc.

It is not probable that any of the foregoing occurrences could start an ulcer in the absence of hyperacidity which always remains the condition *sine qua non*. Aschoff (5) showed in animal experiments that purely mechanical lesions heal very quickly. The majority of these small patches of toxic-infectious necrosis heal readily when general infection subsides and when the toxemia is not too great. This is proved by the great number of scars found in the gastro-duodenum at necropsy (in 10 per cent of all cadavers, according to Hurst and Stewart (7).

The occasional causes are not essential; the gastric juice, if strong enough at a certain point, can probably start an ulcer without extraneous help. Nevertheless, if abnormal acidity prevails, the occasional causes will favor ulceration and will mark its beginning, thereby becoming contributory factors of considerable importance. (Indeed, it is an open question whether the lesions caused by roughage, abuse of spices and stimulants, etc., when constantly repeated, may not set up a local inflammation of the mucosa and a chronic irritation of the gastric nerves, so as to bring about, by reflex, an increase of the acid secretion. This, in turn, would produce an ulcer. We shall discuss this point under "final" causes). As we do not know which patients are hyperacid, or will become so in the course of time, it is always better to prevent or to correct the action of the occasional causes by proper diet, by removal of foci of infection, by gentle technic at operation, avoiding mass ligatures of the omentum, etc.

III. THE FORMAL CAUSE

We do not attach much importance to the form or appearance of individual peptic ulcers; they are essentially the same as those of ulcers in various other regions of the body.

The distinctive feature of the peptic ulcer lies in its localization along the lesser curvature (the gastric pathway of Aschoff) (5), and on either side (gastric and duodenal) of the pylorus. The distribution and extent of the process are determined by the peculiar shape of the stomach and the mechanism of the pyloric sphincter. Nature made the antrum like a funnel tapering toward a narrow orifice, the pyloric strait, which opens and closes intermittently, in order to maintain a proper titre of hydrochloric acid during the function of digestion. According to physiologists (8) we have here *a self-regulating mechanism* by which the freshly secreted gastric juice of 0.5 per cent strength is brought down to an acidity from 0.15 to 0.2 per cent in strength by regurgitation of the pancreatic juice into the stomach—at least such is the case in healthy subjects.

In disease, however, the situation becomes quite different: if the pylorus fails to open properly, the titre of the gastric chyme remains too high and the strong acid will burn a hole in the mucosa of the stomach or in the wall of the duodenum when suddenly projected into it. This special conformation of the antrum and of the pylorus is the factor that localizes the ulcer along the lesser curvature and on one side or the other of the sphincter: as such we consider it the *formal cause* of the ulcer.

Many special methods have been devised to correct this condition, all with the same object in view, namely to circumvent or to suppress the pyloric "strait" so as to neutralize the action of the gastric chyme by an increased regurgitation of the duodenal contents into the stomach. The main types of operations recommended as gastroduodenostomy, gastrojejunostomy and partial gastrectomy.

It is not the purpose of this paper to enter into the question of surgical technic in this connection. Each type of operation, as well as each modification of the various technics employed, has its adherents. In any event, the indications for gastric surgery must be established with very great caution and with due consideration of the many factors which must influence a decision, for example: deformity of the stomach, the intractability of the ulcer, the possibility of malignant degeneration, hemorrhage, perforation, the age of the patient, his general condition, and so forth.

Surgical intervention, so often thought of as "radical" is, in reality, very largely palliative. It is directed toward the formal cause of ulcer, namely the peculiar shape of the antrum or the pylorus, and its object is to prevent the formation of a pool of strong acid in the antrum. In achieving this, it partially neutralizes the gastric chyme *after* it has been secreted and so, indirectly, it acts also against the efficient cause, that is, the secretory power of the stomach. Operation, however, does not strike at the source of the acid production, nor does it attack the final cause of the disease. This is the weak point in gastric surgery, and this is the reason it is not always suc-

cessful. Medical treatment, therefore, remains the basis of all our therapy, and operation should be considered only as an adjuvant to internal medicine.

IV. THE EFFICIENT CAUSE

As such we consider the nervous energy, especially the neurosecretory mechanism governing and regulating the output of hydrochloric acid, which itself is only an agent and a part of the efficient cause. It is the disturbance of this mechanism which actually produces the peptic ulcer.

As component parts of this apparatus we have: the gastric glands and muscle fibers, the plexuses of Meissner and Auerbach, the sympathetic ganglia and trunks with the rami communicantes, the spinal cord, and finally the central nervous system, which has also, through the nervi vagi (X) another more direct connection with the stomach.

The gastric juice or chyme is produced during the process of digestion, (the total amount being 1 or 2 liters a day): at the same time peristaltic waves, moving at the rate of about 3 a minute, mix the acid with the food; the pylorus, acting as a regulator (8), opens from time to time and allows some regurgitation of the pancreatic juice into the stomach. Then (and this is also an important function of the nervous mechanism) when digestion is completed the supply of hydrochloric acid is shut off so that normally none should be found in the empty stomach.

The activity of the nervous parts is influenced by various factors, such as local irritants, peritoneal inflammation, central (psychic) stimuli, hormones, alkaloids, etc. (9, 10, 11).

From all the experiments that have been made and all the opinions that have been advanced, we are inclined to believe that there are two distinct portions of the nervous system involved in the function of digestion.

1. The "vegetative-reflex" portion, consisting of the peripheral nerves and spinal arcs, with the interposition of the sympathetic chain acting as a sort of shock-absorber in both directions, the whole being connected with the brain by tracts of the spinal cord, but working with a certain degree of autonomy.

2. The central portion (cerebral centers and vagus nerves) which normally has only a small participation in the process of digestion, though on certain occasions, the psychic stimuli enter into play and are transmitted to the stomach by the tenth nerve. If the action of the vagus is deficient (depression, apathy) there may be atony of the stomach; if it is excessive (fright, excitement, over stimulation) there is increased peristalsis, spasm, hypersecretion, even pyloric closure with vomiting, etc.

The Neurogenic Theory of Peptic Ulcer: Rokitanskey (cited by Cushing (10) was the first to teach that certain peptic ulcers are caused by *"a diseased innervation of the stomach, owing to a morbid condition of the vagus causing extreme acidification of the gastric juice."* This point was brilliantly demonstrated by Cushing in a series of cases of brain tumor complicated by gastric ulcer, some of them with perforation. In the overwhelming majority of cases the alteration in the nervous center is only functional (excessive stimulation) but nevertheless its effects are severe and the theory of the neurogenic origin of peptic ulcer has gained ground steadily. Eppinger and Hess (12) supported it by their studies of vagotonia. Von Bergmann (11, 15) and his pupils did much to foster this theory. They also called attention to the anemic patches with consequent ulceration caused by occlusion of the vessels as a result of intense muscle spasms. Hurst and Stewart (7) also speak of a "hypersthenic" gastric diathesis.

Theoretically, the nervous disturbance may originate either in the peripheral vegetative reflex part or in the central part of the nervous system. (We shall return to this point under the discussion of the final cause). As a rule, however, we may say that the vegetative reflex system behaves like an honest laborer doing his work in a humble, unspectacular, orderly manner, while the central nervous system may be likened to a labor agitator intent on sabotage and constantly striving to drag the other fellow away from the regular performance of his duty. By interfering with the quiet, automatic, clock-like process of digestion, the central nervous system acts as a troublemaker and a disturber of the peace.

PATHOLOGY

Secretion: The essential factor in the formation of ulcer is a change in the secretion of hydrochloric acid by the stomach. We call it "hyperacidity" which may not be quite accurate. Von Bergmann (13) investigated the exact titre of acidity in a large series of patients and found the following:

	Gastric ulcer	Duodenal ulcer
Hypoacidity (anacidity)	35%	0%
Normal acidity	41%	57%
Hyperacidity	24%	43%

These findings indicate that only a minority of patients with peptic ulcer have actual hyperacidity. The serious aspect of the change in secretion lies not so much in the amount of acid formed as in the time of secretion and the fact that acid is found in the empty stomach, especially at night. It is the *bad timing* of the acid production, a dysfunction of the neurosecretory mechanism, which constitutes the outstanding phenomenon of ulcer. The nervous system may be compared to a careless watchman who is supposed to control a certain faucet but fails to do so; in the case of gastric ulcer, the "watchman" opens the faucet of secretion too early, before there is enough food in the stomach to neutralize the hydrochloric acid which pours into it; the consequence is pain as soon as the patient begins his meal, though he usually is fairly comfortable between and before meals. In the case of a duodenal ulcer, the "watchman" forgets to close the faucet tightly after digestion is complete, acid keeps trickling down the walls of the stomach causing much spasm and pain which the patient feels four, five, six or more hours after meals. It is most troublesome at night, usually waking the patient at 1:00 or 2:00 a.m. Ingestion of food relieves the pain. It seems that food absorbs the hydrochloric acid like a sponge and so protects the mucosa, but if acid is secreted between meals there will be pain and danger of ulceration. Bockus (14) found this "postprandial" acidity in 84 per cent of the patients with duodenal ulcer.

Sensation and Motility: The first effect of the presence of hydrochloric acid in an empty stomach is to cause pain of spasmodic nature (15), and this is rarely absent. In acute ulcers or in acute exacerba-

tions of chronic ulcers there are often periods of severe, even intense, pain lasting for weeks or months. We may call these periods *acid crises*. The secretory power of the nervous system pours hydrochloric acid into the stomach in large quantities and to this stimulus the muscles — especially the pylorus — react constantly with painful spasms. Once started, an ulcer will also, by reflex, cause more spasm and more secretion. This results in deeper ulceration, and such a vicious circle becomes established that it is impossible to say what was primary, the whole gastric mucosa being in such a state of erethism that even the blandest foods cause irritation and pain.

Treatment of the Efficient Cause: Our chief weapon against this factor has been insistence on a strict diet, with alkaline medication, in order to limit the production of acid and to have it properly timed, thereby protecting the autonomous process of digestion.

Though such provocative agents as stimulants and spices are known to cause much acidity and pain in patients with ulcer, the worst offenders seem to be the animal proteins. Yet it is difficult to do without them, as most people who are active are not satisfied with a purely vegetarian diet.

I have found that a good plan is to give the patient whatever red meat (liver, kidney, boiled beef, etc.) he is allowed to have, at his breakfast; during the morning he may carry some chalk tablets with him and eat them in case of pain. He should have a lunch low in protein, with fish or cream cheese or two eggs at the most. Then, and this is the important point — the evening meal should contain no animal protein of any kind, not even cream cheese, eggs, milk, broth or ovaltine. It should consist only of pureed vegetables or fruit and some cereal or paste. A meal of this kind will "mop up" whatever acid has oozed down the wall of the stomach after the previous digestion, but will not start the secretion of new acid in excess, and this is, in my experience, the most efficient single measure by which the patient may regain his much needed sleep.

This medical treatment, though usually successful, is not uniformly so because it does not correct the final causes of the trouble.

For some reason difficult to understand, most of the advocates of the neurogenic theory have failed to draw the full conclusions from their premises. If gastric secretion is under the control of the nervous system, and if a peptic ulcer is a manifestation of a derangement of that system, it follows logically that, in order to cure this condition, we should make our frontal attack against the factors injuring the nerves, i.e., against the *final causes*.

V. THE FINAL CAUSES

The final cause is the purpose or the end of a thing, the last "instance" in the causation of a certain effect. We regard as the final causes of peptic ulcer the factors which whip the neuro-secretory apparatus into an excessive or disordered activity. This dysfunction may affect either the peripheral or the central nervous system.

1. *Peripheral (Mucosal) Nervous Irritation.* When we reviewed the occasional causes of ulcer, we asked the question whether a constantly repeated injury to the mucous membrane could not set up a chronic irritation of the peripheral nerves and in this way start an excessive secretion of gastric chyme. This may be possible. Yet, when we consider the abuse to which many alcoholics subject their stomachs without showing signs of ulcers, and remember the excessive use of spices by certain races, without apparent increase in the incidence of gastric ulcers, we hesitate to raise these occasional occurrences to the dignity of a final cause. If we correct the diet of these people, the majority of them get better, but in many the symptoms persist, showing that other forces are at work to keep up the abnormal secretion of acid.

II. *Reflex Irritation of Abdominal or Peritoneal Origin:* In another group of cases, the nervous dysfunction has its origin in some residual focus of peritoneal inflammation, chiefly in the appendix, gall bladder, or pancreas, but also — though rarely — in the pelvic organs, in diverticula, in the kidneys, etc. We regard these not so much as possible foci of infection, as we do sources of irritation resulting from inflamed organs with contents under tension, stenosis of the walls, kinks, or firm adhesions to important structures (intestine, ureter, nerve trunks, etc.). Any of these states of chronic peritoneal irritation may cause some reflex neurosecretory disturbance with reflex dyspepsia and hyperacidity, reflex pyloric spasm, cramps and all of the symptoms of peptic ulcer, including hemorrhage. Such reflex irritation as a cause of peptic ulcer has been accepted by many authors (7, 16).

Among our patients with ulcer, we meet a certain number of persons of primitive type—laborers, farmers, etc.—who lead a sort of "vegetable" life, doing no thinking, having no cerebral activity or mental worry of any kind. It is evident that, in people of this type, the nervous disturbance of secretion cannot be explained by any influence of the central nervous apparatus but is caused by reflexes originating in the abdomen. Some of these patients are so dull in their sensations that, occasionally, we are called to see them for hemorrhage or a perforation as a first sign of an ulcer of which they had no slightest premonition. It should be remembered, however, that foci of chronic peritoneal irritation may also exist in the intellectual persons along with the disorders of the central nervous system. At any rate, it is our duty, especially in patients of low mental development, to search diligently for residual inflammations in the peritoneum as possible sources of these reflex phenomena; it is only by eradication of these old inflammatory lesions that the gastric symptoms can be relieved in patients of this group.

III. *Central Nervous Disturbances:* In this very large group of patients, with functional disorders of the central nervous system, the final cause is represented by all the noxious factors of modern life which keep our brains in a state of continual tension: economic and financial fears and worries; heavy responsibilities; cut-throat competition; the necessity of doing things at great speed with undue excitement; lack of rest and of sufficient relaxation, especially during the time of digestion. The central nervous system, struck by the constant pounding of these injurious forces, will itself repercuss on the different organs along certain paths; why this repercussion should, in certain cases, fall on the stomach, in others on the intestine, or the heart, or the thyroid, we do not know. We study its action on the gastro-duodenum here solely because we are especially interested in this aspect of the problem on account of its frequency at the present time.

Prophylaxis: Owing to the enervating influences of the present day, we have become an emotional race craving sensationalism and thrills of all kinds. We yield too quickly to excitement and to uncontrolled impulses. It should be possible by education, by mental hygiene, and special training to cultivate in our children strength and firmness of character, as the ancients did, so as to permit them always to keep their nervous balance in adverse and difficult situations.

The Management of Cerebral Activities in Patients with Ulcer: Some writers—Von Bergmann (11, 15), Rivers and Dry (17), and others have already advocated the control of the neurogenic factors in the treatment of this disease. I go further; I believe that the brunt of our attack should be directed against these final causes constantly injuring the nervous system, and that the patient should be given much more detailed and specific instructions as how to regulate his mental activities, especially during the periods of digestion.

Major shocks such as the death of a relative or friend, financial reverses, severe bodily injuries, are all fraught with great danger as they may lead to a prolonged acid crises with hemorrhage, disability, etc.

In such occurrences the physician and the family of the patient should do their utmost to divert his mind, soothe his pain, and encourage him in any possible way. A trip or a change of environment may be very necessary at such a time.

Outside of these great misfortunes, however, there are all the minor shocks and annoyances of every day life: errors, delays, interruptions, trifles of all kinds, details of work that may be left to a secretary, and much unnecessary excitement that one should avoid. There are also matters involving our personal pride and ambition, speculation, gambling, etc., and risks of every kind. The patient with ulcer should leave these things severely alone. By planning and determination he should learn to keep away from all non-essentials, thereby reducing the sources of irritation to the minimum so as to preserve the tone and fitness of his nervous system.

The Division of Work: As a general rule, heavy mental work should be done as late as possible after meals, or only after a very light meal.

Mental activities should be divided in two parts: (a) the routine work might be started one hour after meals, and (b) the strenuous work that should not begin before three hours after meals. If this cannot be done, the midday meal should be much curtailed and the patient could eat more at night when he is through with his duties. Personally, I like to do any heavy work, such as reading an important book or paper, preparing a speech or memorizing a lecture, drawing the final conclusions of an article, etc., early in the morning between five and seven; two hours of cerebral activity of this kind are enough and the rest of the day should be given to routine work only. For a business man who has to do his most concentrated thinking in the middle of the day, things may have to be arranged differently; it is better for him to sleep longer in the morning, have a quiet breakfast, walk leisurely to his office, a part of the way at least; then begin the day with the routine work, looking through his mail or talking to employees about his affairs in general, etc., reserving the more strenuous work for the hours from 11:00 a.m. to noon, and 4:00 to 5:00 p.m. If the pressure is such that heavy work, important conferences and the like must be resumed early in the afternoon, a very small lunch or no lunch at all should be taken.

The meal hour should be spent in pleasant company and in light conversation: some men invite their friends to lunch in order to discuss serious problems; some even have that meal served on a tray in the office while they keep studying important matters. No wonder their digestions are disorganized! The best plan would be for the patient to lie down or have a quiet stroll after meals; at least there should be no exertion at that time.

The Question of Rest: The evening should be left to relaxation, quiet games, etc., and a man should certainly not select a hobby that is more strenuous than his regular occupation as some people do.

Those who can afford it should take a complete week-end rest or a vacation as often as possible.

Mental rest and relaxation should be the keynote in the treatment of peptic ulcer.

The execution of the foregoing program may prove a very arduous matter for the physician in charge; he must secure the cooperation of his patients many of whom will say to him, "It cannot be done." This disease is so hidden and so insidious that they will not see it; they will not admit it; some will rebel and throw away all dietetic restraint. We even see physicians adopting this foolish attitude—as if the fact that we ignore an organic lesion could contribute to its cure! If such a man finally suffers a severe complication, a prolonged acid crisis, or a profuse hemorrhage, with months and years of enforced idleness, he will become more amenable to reason and persuasion. If he has to provide for dependents, he will see that in order to live and to work a few years longer, our plan is worth something after all, even if it entails heavy sacrifices of his pleasure and his mode of life and, by trying, he will find that it *can* be done.

In this last chapter, we have merely sketched the general plan of treatment. If an alert internist or neurologist would undertake this task of drafting a schedule of work, designed to protect the local function of digestion from the disturbing influences of the central nervous system, and do it in such a way that it could be adapted to the different professions, according to their special requirements, he would render a signal service to the business world in general.

SUMMARY AND CONCLUSIONS

1. An attempt is made, by following the ancient classifications, to analyze and evaluate the various causes of peptic ulcer.

2. The material cause—the biological structure of the tissue—may still be considered an uncontrollable factor.

3. The occasional cause—changes in the tissues arising from trauma or circulatory disturbances—are important, but it is doubtful whether they can start an ulcer in the absence of abnormal acidity.

4. The formal cause—the shape of the stomach and the mechanism of the pyloric sphincter—is treated by various types of surgical operations which do not obtain an absolute percentage of good results because they act only indirectly on the efficient cause (secre-

tion of acid) and do nothing for the main or final cause.

5. The efficient cause — hyperacidity — is counteracted by our dietetic prescriptions, but the results are often incomplete because this therapy also does not affect the final cause. Attention is called to the "bad timing" of the acid secretion as an essential feature and to the appearance of prolonged acid crises. Emphasis is laid on the neurogenic theory.

6. The final causes are discussed and a possible line of treatment is suggested regarding the regulation of mental activities in such a way as to protect the local mechanism of digestion against the inroads of the central nervous system.

Intestinal Motility in Rats Anesthetized with Ether*

By

GEORGE A. EMERSON, M.S., Ph.D.

MORGANTOWN, WEST VIRGINIA

IT has been demonstrated through fluoroscopic observations (1) that ether and chloroform anesthesias are accompanied by a decrease in tone and arrest of movements of the entire gut. Miller (2), working with dogs having balloons in permanent fistulae of the stomach, small intestine and colon, has shown that with ether anesthesia all stages are accompanied by diminution or loss of tone and contractions except the transitory so-called "excitement," or delirium stage. During surgical anesthesia he found both complete inhibition of most of the smaller contractions and entire lack of peristalsis, as noted at all three fistulae. Sleeth and Van Liere (3) have demonstrated a marked increase in gastric emptying time of etherized animals. Following anesthesia, Miller (2) found that the colon may become hypertonic or spastic and that the small intestine shows exaggerated activity, while the stomach may remain somewhat atonic for five hours or more.

Macht's method (4) of studying intestinal motility in rats was introduced as a technique for the comparison of cathartics, but is equally well suited for studying other factors influencing intestinal motility. Like the roentgenographic methods, it measures only the *effective* motility of the gut, and so is perhaps more likely to yield results applicable to practical conditions in the human than are some of the other physiological techniques. In order to obtain a quantitative picture of the effect of ether on effective intestinal motility, Macht's technique was used in the following experiments. No variations were made from the technique as previously employed (5).

EXPERIMENTAL

Ten rats, weighing approximately 200 Gm., prepared through a standard treatment, were given 2.0 c.c. of a charcoal emulsion in gum acacia solution intragastrically and were sacrificed by a blow on the head 50 minutes after administration of the charcoal. The progress of this test meal in the intestinal tract between the pylorus and anus was measured and calculated in per cent of the tract traversed. The average value for these 10 control animals is noted in Table I.

Similar groups were treated likewise: (a) 10 minutes after induction of ether anesthesia in a chamber of 18 L. total capacity, containing an initial concentration of 2.5 mM L. of ether in oxygen; anesthesia with the same tension of ether was then resumed and continued 50 minutes, when the animals were sacrificed and examined; (b) immediately after 60 minutes of anesthesia with the same initial concentration of ether; and (c-h) at various periods after anesthetization for one hour with ether at the same initial tension, up to 48 hours. Averaged results for each group of 10 animals are collected in Table I.

As the rats were of approximately the same body weight in all groups, and the same number of rats was used in each group, the depth of anesthesia over the period of an hour may be considered very nearly the same for all groups since variations in the amount of ether absorbed by the rats would be negligible. Objectively, no difference in the depth of anesthesia of the various groups could be noticed. In all cases, the ether mixtures were made up with oxygen, and accumulation of carbon dioxide in the anesthesia chamber prevented by keeping a large gauze bag of moist soda-lime in motion during the period of

Submitted November 5, 1936.

anesthesia. The effectiveness of these measures in preventing anoxemia or excess of carbon dioxide is reflected in the results collected in Table I.

DISCUSSION

From Table I, it may be noted that suppression of effective peristalsis in the small intestine is very marked during the period of anesthesia. In only one case did the test meal traverse more than 10% of the intestinal tract during anesthesia. Measurement of the passage of the test meal was difficult in animals tested during the first hour after anesthesia, since scattered small portions of the test meal, which appear as small specks through the intestinal wall, were carried along to about half the length of the intestine in a small number of rats and so increased the average figure. The value obtained for motility during the first post-anesthetic hour is therefore probably misleadingly high, due to the occurrence of weak peristaltic rushes toward the end of the test period.

Only in experiments done in the second post-anesthetic hour and thereafter is the normal appearance of a solid column of material contained in the gut obtained, denoting the resumption of normal strong peristalsis. This delay in recovery of intestinal tonus and peristalsis is not surprising, for the rats remain lightly anesthetized for as long as 20 minutes after ether administration is stopped, indicating that the tissues have become well saturated with ether during the long period of deep anesthesia.

The use of 10 animals for each test by Macht's technique has been recommended, and a comparison of control values in Macht's (4) and other (5) series with the present findings indicates that excellent agreement may be obtained using this number. Tolerances noted in Table I represent one standard deviation of the mean. It may be noted that only the experiments done during anesthesia and the first, second and sixth post-anesthetic hours differ significantly from the controls.

TABLE I

Action of ether on the motility of small intestines, Macht's Method. Results expressed as per cent of intestinal tract between pylorus and anus traversed by a test meal in 50 minutes

Untreated	During Anesthesia	Hours after 60 minutes anesthesia						
		1st	2nd	3rd	6th	12th	24th	48th
55 ± 2	3 ± 1	30 ± 3	48 ± 2	60 ± 2	63 ± 2	57 ± 3	57 ± 2	55 ± 3

SUMMARY

Surgical anesthesia with ether inhibits the motility of the small intestine of rats for the period of its duration. Recovery is rapid after anesthetization with ether for one hour, and the gut regains approximately its normal activity by the second hour after anesthesia is terminated. Some slight hyperactivity may occur from the third to the sixth post-anesthetic hours.

NEWER METHODS OF TREATING HEMORRHAGE DUE TO ULCER

AT the 16th Scandinavian Congress for Internal Medicine held at Uppsala in 1933, Meulengracht made his first suggestion and reported his first results obtained by treating hematemesis and melena by giving the patient "something to eat." Subsequently, in 1934 and again in 1935 he reported larger series of cases with exceptionally good results in spite of his seemingly radical procedure of continuing a full and varied diet throughout the period of active hemorrhage and during the post-hemorrhage convalescence. He treated 251 ulcer cases with only 3 deaths, a truly splendid record (1.2%). The diet consisted of pureed and soft foods and the free administration of alkalies. Dinner alone included meat balls, broiled chops, omelette, fish balls, vegetable soup, stewed apricots, apple sauce, the patients eating "as much as they want."

This is a brave, very brave, frontal attack upon hemorrhage by the manoever of free and plentiful feeding, a procedure which affronts our previous orthodox concepts of enforced rest for the injured parts, physiological quiet, the free use of morphine and abstention of all food and drink by mouth. But since this is the day of radical attack upon orthodox tradition, it behooves the older members of the conservative party to pay close attention and weigh carefully the merits or demerits of such a proposal before accepting it precipitately or denouncing it without trial.

Meulengracht has quoted the mortality figures for the treatment of ulcer hemorrhage by various older authors as Bullmer 10.7%, Chiesman 25%, Tidy 19%, Hinton 20%, Lynch 12.9%. This is of course painting a very black picture, hardly consonant with all the facts.

Thus Chiesman as recently as 1932 had a mortality at St. Thomas' in London of 27% of 191 cases, but

transfused only 15 patients! At least 36 patients died of fatal hemorrhage without transfusion. The series of Lynch comprised only 31 cases (12.9%) mortality); that of Hinton, 50 cases (20% of deaths), both series being rather small and exceptionally unfortunate.

On the other hand, with the older methods of starvation and sedation, Hurst reported a mortality from Guy's Hospital, also in London, of 2.5% of 600 cases; Nielsen, also from a Scandinavian country, one death in 182 ulcer cases, Paterson, 3.8% mortality in 124 cases, and Crohn and Manheim, a fatality rate of 4 deaths in 94 gross ulcer hemorrhages 4.2%.

It is true of all such controversial medical literature that figures can often be cited to uphold a viewpoint, and another set of figures to confound it, each of the parties acting in good faith and citing authoritative publications. But if nine justices can divide frequently five to four on an interpretation of a statute, how easily for medical men to differ when attempting to decide upon a point of applied rather than pure science, when hoping to draw the truth from a concise publication tinctured by the personality and biases of the writers.

A word of caution before applying this newer philosophy of free feeding to freely bleeding ulcers might well be in place. The older methods of starvation and rest were apparently very satisfactory in the hands of the older experienced physicians. It was a sagacious generation that had learned by bitter experience that to feed during the lull of a fast hemorrhage was often to invite a brisk recurrence perhaps with fatal issue.

Science is never a closed page, anyone has the right to reopen an issue for reconsideration. But before the left-wing radicals put into large-scale practice this rather novel suggestion of full feeding, it might do well to stop and ponder possible direful consequences of such a seemingly rash procedure.

No one would question the brilliant therapeutic results of Meulengracht himself in skillfully feeding gross hemorrhage; no one need question the past experience of physicians who starved and rested their bleeding patients with most satisfactory results.

It is to be feared that a sudden reversal of an accepted cautionary practice may, in the hands of clinicians less experienced than Meulengracht, lead to results that may be unfortunate.

This is meant as a word of caution rather than as a discouragement of a therapeutic suggestion.

Burrill B. Crohn, New York, N. Y.

HOW DO BULKY FOODS RELIEVE CONSTIPATION?

THERE is still need for information as to the way in which certain substances given by mouth increase the bulk of the stools or otherwise relieve constipation. Thus one commonly reads that hydrocarbon oil relieves constipation by lubricating the bowel, but anyone who has ever watched the muscular contractions of the bowel and the way in which the fluid contents are moved onward from one segment to another will find it hard to see how lubrication can possibly help the process. In fact it should hinder it much as a slippery field makes it harder for a football team to push onward toward the goal. Lubrication could be of service only if a solid cylindrical plug were moving through a rigid tube with a diameter slightly greater than that of the plug.

Actually the surface of the bowel is well lubricated with mucus and other secretions, and if it were not it still would be hard to see how the taking of oil could facilitate the movements of liquids through a soft muscular tube which contracts peristaltically. It is doubtful if anyone yet knows just why hydrocarbon oil tends to relieve constipation. Perhaps it helps partly by producing a more cylindrical stool which can be extruded more easily. According to Contoléon and Joannidès (1), and Mellanby (2), it may act also by interfering with absorption in stomach and bowel. This interference with absorption may account for the observation of some persons that a dose of hydrocarbon oil, taken before a cocktail party, will go far to give that extra tolerance for alcohol which is so greatly desired by many.

But more important than physical factors may be the chemical ones. Thus there are reasons for believing that the chemical composition and the pH of the fecal residues as they reach the rectum can have much more to do with causing or relieving constipation than does the bulk or consistency of these residues. As every person knows who has ever suffered with constipation, the dry, ovulated type of stool seems to be quite without that stimulating effect on the mucosa of the rectum which normally tends to start the process of defecation.

At other times, in the same person, the feces will so irritate the rectum and so stimulate the defecatory reflexes that evacuation can be restrained only with considerable discomfort, or a soft stool will be so irritant that defecation cannot be put off for more than a few minutes. Significant, doubtless, is the fact that when such material is voided the anal ring often feels scalded and raw as if it had been burnt by some escharotic.

There is still need for research that will show what the substances are which so stimulate the rectal mucosa. One would like to know where and how they are formed, and, if they come from the upper part of the small bowel, why they are carried down unchanged into the colon. Moreover, why is it that some diarrheic movements do not irritate the anal ring while others seem to the patient to be full of Cayenne pepper?

A number of observers have puzzled also over the surprisingly large increase in the bulk of the stool which can sometimes be produced by giving a small amount of agar or other hygroscopic substance. When they applied quantitative methods to the problem they found that sometimes the increase in the bulk of the stools was larger than what could be accounted for by any amount of water which could possibly be imbibed by the quantity of gummy substance given. The puzzle became even greater when it was found that more than half of the supposedly indigestible jelly had been broken up by bacteria and lost on the way through the bowel.

There is another curious puzzle which has not yet been faced and studied as it should be and this is why, when one starts taking agar or some other bulk matter, one often for a while gets an excellent laxative effect, with voluminous stools, and then, after a few days or weeks, becomes constipated. Evidently the bowel is

able to make some adjustment so that it can take the water away from the hygroscopic substances used. Much work needs to be done on this problem because here lies one of the worst stumbling blocks in our therapeutic path. The constipated can often be relieved, but many fail to stay cured unless perhaps the physician is wise enough to have them shift every two weeks or so from one type of bulk producer to another.

Most helpful and thought-producing are some studies made during the last few years by Olmsted and his associates. In beginning their investigations they had first to work out a satisfactory method of measuring the amounts of cellulose, hemicellulose and lignin in foods and feces. Unfortunately, in the past, these three groups of substances have been lumped together under the heading of "crude fiber," and worse yet, the method used for estimating crude fiber in foods and fecal residues did not give accurate results. As Olmsted has now shown, it is important that vegetable roughage be divided into celluloses, hemicelluloses and lignins because they differ not only in the way in which they go through the digestive tract, but also in their ability to increase the bulk of the stool, and therefore in their value in relieving constipation.

Of the three groups of woody substances found in vegetable foods, the hemicelluloses are the most easily broken down by the bacteria of the bowel. Some of the end results of this fermentation, identified as fatty acids, appear to supply about a quarter of the caloric needs of grazing animals.

Curiously, Williams and Olmsted (3) found that pure cellulose is not a good substance for the relief of constipation because it hasn't much power to hold water and thus to increase the bulk of the stools. Taken in the form of cellu flour about 7 per cent of the cellulose disappeared in the stools of the medical students who served as test subjects. Only from 3 to 12 per cent of the lignin in food disappeared, but of the hemicelluloses, up to 80 per cent disappeared on the way through the bowel.

Agar, which is about 80 per cent hemicellulose, did not disappear in the bowel to the extent that one would think it would because of its composition. Actually in some experiments only 48 per cent of the cellulose and hemicellulose of agar disappeared. Perhaps because agar is able to hold much water it proved to be the most effective of the several substances experimented with in increasing the bulk of the stool and relieving constipation.

It appeared, however, that this effectiveness of agar was not all due to its hygroscopic property. Much of its laxative effect seemed to be due to the retention in the stools of some of the lower volatile fatty acids which result from the bacterial digestion of the hemicelluloses. As is well known to pediatricians, fatty acids in the stools can have a laxative effect. Puzzles remain, however, because those who have put fatty acids into the lumen of the bowel of animals have not always observed a stimulating effect (4, 5).

More work needs to be done also before it is known why certain fruit juices and certain fruits such as prunes and figs are mildly laxative. Some experiments made years ago with prunes and other fruits made me suspect that the pectins may be responsible for some of the laxative action. Curiously, commercial solutions of pectin seemed to be decidedly laxative for some persons but not for others. Recently some experiments have reported the presence of a laxative in concentrated prune juice. Years ago when I searched for it I could not find it.

A PLEA FOR CONSERVATISM IN THE INTERPRETATION OF GASTROSCOPIC FINDINGS

DIRECT visualization of the interior of organs connected with the various orifices of the body has increased the accuracy of diagnosis and has broadened the field for efficient therapy.

The most recent instrument of this type which has been introduced is the Wolf-Schindler gastroscope. The ease and safety with which this instrument can be passed into the stomach and the excellence of the views of the gastric mucous membrane which may thus be obtained make gastroscopy desirable in many patients who suffer from disorders referable to the stomach. As with other similar innovations in medicine, there is a tendency to overemphasize the importance of insignificant changes which may be observed and to attribute many symptoms to these apparent deviations from normal. One must remember that symptoms referable to the gastro-intestinal tract occur with great frequency in patients who suffer from nervous instability. To attempt to attribute these symptoms to "gastritis" on the basis of minimal changes in the mucous membrane of the stomach, which may sometimes be observed through the gastroscope, will lead to disappointment in treatment and will serve to discredit an instrument which appears to have value in the more accurate diagnosis of gastric diseases.

Porter P. Vinson, Richmond, Va.

THE PLASMA PROTEINS AND LIVER DISEASE

HYPOPROTEINEMIA is, as a rule, the result of one of three conditions: inadequate dietary intake or actual starvation, unusual losses of protein due to albuminuria or severe diarrhea, or failure of intestinal absorption of protein-forming substances, as noted in sprue or in the presence of gastrojejunocolic fistula.

The idea that hepatic lesions might be attended by alterations in the plasma proteins is relatively new, but there are a number of clinical reports now available which indicate that hypoproteinemia is a fairly constant finding in parenchymatous disease of the liver. In extreme conditions, very low levels of plasma proteins may be found, with albumin-globulin ratios as low as 0.3. In the earlier reports it was assumed that this finding was due to malnutrition, but a review of some recently reported cases indicates that the reduction in circulating protein is not due to abnormal losses, to an inadequate dietary intake, or to lack of absorption. In fact, it has been clearly demonstrated

that a diet high in protein, producing a strongly positive nitrogen balance, does not necessarily increase the proteins in hepatic disease; it has also been shown that losses in ascitic fluid do not materially reduce the plasma levels. By exclusion, therefore, the observed reductions appear to be due to the inability of the body to fabricate these substances, particularly serum albumin, and the liver appears to be responsible in part.

There is considerable experimental evidence to show that this explanation is sound. Reductions in total serum proteins have been noted after experimental injury of the liver and in animals with Eck fistulas. Recent studies from Whipple's laboratory seem to indicate that there is a reserve of protein-building material in the organism which is stored in large part in the liver, and that a large portion of this is either in the form of albumin or of albumin-producing material. It is not, of course, inferred that the liver is the only site of protein synthesis, but there is good reason to believe that the liver probably figures in some mechanism by which a dynamic equilibrium is maintained between stored and circulating protein.

These changes in plasma proteins may have considerable diagnostic and prognostic significance. In recent uncomplicated obstructive jaundice, such as that produced by neoplastic obstruction of the bile passages, the total protein and the albumin-globulin ratio are usually within normal limits. When ascending biliary infection or obstructive cirrhosis complicates the picture, the total protein is definitely reduced and the albumin-globulin ratio decreases steadily. In the severest type of acute parenchymatous hepatic injury, such as that seen in portal cirrhosis, the total protein may be low, the so-called edema level, and less than 25 per cent of the total amount will be albumin. These changes are reversible and normal values for total protein and albumin-globulin ratios are found as recovery takes place.

Enough is known of the relation of plasma proteins to the distribution of the body fluids to assure us that the low levels seen in hepatic disease are not without some effect on the production of ascites and edema. Physical measurements appear to show that the albumin component of the plasma proteins is chiefly responsible for their osmotic effect, the globulin fraction being relatively unimportant. While it must be admitted that the "salting" process by which the two proteins are separated is somewhat imperfect, the error of the method is probably not as great as the variations which have been observed in clinical cases. Recent measurements of the osmotic pressure of the serum of patients with hypoproteinemia secondary to hepatic injury indicate not only that the total osmotic pressure is low, but that the unit pressure per milligram of nitrogen content is also reduced. It seems quite likely, therefore, that the development of ascites and edema in hepatic disease depends, to a large extent at least, upon changes in the serum albumin and upon the effects which such changes produce on the osmotic pressure of blood serum. Quite possibly, as Rosenberg has noted, the increased size of erythrocytes, which may be observed very early in the course of clinical cases of hepatic injury, is due to this same decrease in osmotic pressure.

There are so many unknown factors in regard to hepatic insufficiency that any studies of these alterations in circulating protein and the effects on water and electrolyte distribution secondary to them cannot fail to give information of clinical and physiologic importance.

A. M. Snell.

BRIEF REVIEW OF THE PAST AND FUTURE OF GASTROPHOTOGRAPHY

IN the development of gastrophotography two distinct periods may be distinguished. In the first period the chief goal was that of safely establishing a morphologic method for the diagnosis of lesions of the gastric mucosa. Lange of Munich was the first to introduce a small photographic camera attached to the tip of a rubber tube into the stomach (1898) (1). By the development of the rigid gastroscope a multitude of pathologic pictures was revealed and became known, especially by the publication of my gastroscopic "Atlas" published in 1923 (2). Since gastroscopy with the rigid gastroscope was a dangerous method, safe only in the hands of a few experts, the efforts to come to another morphologic method for diagnosing gastric diseases were continued. I greeted the invention of the gastrophotor (1929, Heilpern, Back and Porges) (3) with greatest enthusiasm, and for three years I tried to photograph the interior of the stomach. Henning, of Leipzig, did the same. It seems that we were the only workers to check gastrophotography by gastroscopy with its distinct and undeniable pictures, but both of us after long efforts decided that the method was unreliable and of no use at all (4, 5). There were three difficulties: (1) One never knew which region of the stomach had really been exposed, a drawback, foreseen as early as 1897 by Kelling, and one which could be overcome only by photographs taken through the gastroscope: "aimed exposures." (2) The pictures were generally blurred. This obstacle could be overcome by further development of the apparatus. The newest book of Heilpern, and also most of the recent papers are as disappointing as were the first books by Bécart (6) and Bernay (7) (both 1931), but Garin and Bernay, of Lyon, are now working with a Lens-bearing apparatus, and pictures shown by Rehfuss, Philadelphia, were entirely sharp. (3) The most color-sensitive or panchromatic films were not able to reproduce the slight differences in color in the decisive part of the spectrum between yellow and red, which are of the greatest diagnostic importance. In one of my papers (8), I reproduced the picture of a large benign ulcer, a photograph made through the rigid gastroscope with Henning's camera. The surface of the ulcer, gastroscopically brilliant yellow of color, was the same grey as the adjacent mucosa which gastroscopically was orange-red. The ulcer could be recognized on the film because of its one undermined edge casting a dark shadow. After the introduction of the flexible gastroscope, gastrophotography with the blindly working gastrophotor has become obsolete as everybody will notice who has worked for years with both methods. Based on the numerous findings with the flexible gastroscope a new "endoscopic pathology" of the stomach has developed. Gastrophotography, in its present stage can not even try to imitate these most definite results. The fact that gastroscopy is an office procedure and has spread as such, in a few years over all countries with unbelievable rapidity proves that

gastrophotography now has come into a second stage. The black and white picture cannot compete with the easily obtained direct aspect of the colorful gastric mucosa, but it may provide us with *objective records* of at least a part of our gastroscopic findings. This can be done only by photographing through the flexible gastroscope. Until now the light of this instrument was not sufficient to permit aimed photography, but this is a minor technical question to be solved in a short time. This type of photography would not be of diagnostic value, but it would give us some permanent records. Entirely satisfactory results will not be obtained in the near future. It is important that neither the urologists nor the proctologists routinely photograph their findings although this type of photography would be much easier than gastrophotography, because the mucosa of the bladder and of the rectum do not move as the gastric mucosa does by the respiratory movements of the stomach. All depends as to whether films of sufficient color sensitiveness will be available. It seems unlikely that colored films will be sufficiently sensitive in the decisive part of the spectrum. The psychological question remains: why do the urologists care so little about making photographs in cystoscopy, while some gastro-enterologists advocate the more difficult photography of the stomach. Evidently they have not as yet realized that they have now an instrument with which they can inspect their organ as successfully as the urologist does the bladder, and that in the great majority of all cases this examination is much less disagreeable to the patient than is cystoscopy in the male. Nevertheless we certainly will continue with our efforts to get documents as objective as the X-ray film, but we will choose that way which alone provides success: photography through the gastroscope.

The Bowel . . . A source of infection

● Any means of safely and effectively reducing fecal toxicity becomes a logical procedure in a host of conditions.

Morris and Dorst, Burger and other investigators have demonstrated the fact that toxic absorption from the enteric tract may be decreased by the oral administration of Soricin.

When given in adequate dosage over a reasonable period of time, Soricin brings relief in the treatment of mucous colitis, ulcerative colitis, and a large variety of other conditions traceable to fecal toxicity, such as vertigo, anorexia, migraine, urticaria, allergic diarrhea, etc.

Soricin is non-toxic and has no cumulative effect. Large doses may be given repeatedly over a prolonged period of time without untoward result.

Soricin

DOSAGE FORMS: Soricin Capsules—Enteric capsules of sodium ricinoleate, available in five-grain and ten-grain sizes.

Soricin Tablets—Enteric coated tablets, each containing five grains of sodium ricinoleate.

Soricin and Bile Salts Tablets—Enteric coated tablets, each containing four and one-half grains of sodium ricinoleate, and one-half grain of bile salts.

ACTION: Detoxifies in vivo • Desensitizes • Inhibits putrefaction • Prevents toxic absorption.

INDICATIONS: Bacterial Hypersensitivity of the intestinal tract • Intestinal toxemia • Intestinal allergy • Allergic diarrhea • Urticaria—angioneurotic edema • Colitis.

"The Relationship of Calcified Mesenteric Glands to Abdominal Pain." South. Surg. Jour., 5:447-462, Dec., 1936.

Enlarged mesenteric glands in children or adolescents should be classified as either "acute mesenteric adenitis" or 'calcified quiescent tuberculous glands." The symptoms of the former may mimic an acute appendicitis and generally subside after an exploratory laparotomy or appendectomy. They present an entirely different clinical picture from the calcified tuberculous glands which must be considered in atypical cases of chronic or recurrent appendicitis. While these glands are usually demonstrated by an X-ray ex-

amination of cases with questionable diagnosis or by exploratory laparotomy physical examination of the abdomen will show tenderness over the involved glands. The most common area is just above McBurney's point but may extend upward and to the left along the root of the mesentery. Occasionally a definite mass may be felt but there is little if any spasm of the abdominal wall and there is no rebound tenderness. Approximately 50 per cent of patients showing calcified glands will have no symptoms attributable to them and will generally respond well to general hygienic treatment. This is also true of those with mild symptoms especially if the patients are quite young. Many of those having symptoms will have rather frequent attacks of pain usually, however, of only a few hours duration.

In a well-studied small series of cases involving young adults it was definitely shown that a decidedly higher percentage of cures was obtained when these calcified glands were removed at the time of appendectomy. A warning is given regarding the technique of removal; the integrity of the blood vessels of the mesentery must be maintained and no rough area left uncovered by peritoneum. The persistence of symptoms in about half of the cases where the glands were not disturbed is a fact worthy of careful consideration. Fortunately other tuberculous foci in the body are quite rare in this type of infection.

GOLDBURGH, HAROLD L.

Amebic Abscess of the Liver: Report of a Case Without Previous Manifestations of Amebiasis: Operation and Recovery. Ann. Int. Med., Vol. X, p. 926, Dec., 1936.

The author reports a case of amebic abscess of the liver without previous manifestations of amebiasis, with operation and recovery.

The patient, a white male, age 58 years, entered the hospital September 16, 1935, and claimed that a week previously he had noticed a sudden onset of severe pain in the right upper abdomen, griping in character, coming on every hour or hour and one-half and lasting for fifteen minutes. The pain had no relationship to food and was not associated with nausea, vomiting or diarrhea. He had persistent hiccoughing; was chilly, had fever and felt drowsy. The past medical history was essentially negative, and there was no history of contact with carriers.

After the operation and after a month of repeated questioning, the daughter stated that for a period of fifteen years the patient had had recurrent pains in his right upper abdomen. There were attacks of abdominal cramps without diarrhea, coming on twice a week and lasting 24 hours. These pains were relieved in one hour by the taking of a tablespoonful of coal oil with sugar. His son-in-law, who lived in the same house, had been treated for two years for bloody diarrhea, but repeated examinations of his stools had failed to reveal the presence of ameba.

Physical examination: The patient was a slightly emaciated and dehydrated adult male, who appeared distressed. The abdomen revealed moderate fullness in the epigastrium, over which area there was pain and tenderness which was made worse upon breathing. The upper limit of the liver dullness commenced in the fifth intercostal space anteriorly in the mid-clavicular line and extended 6 centimeters below the costal border. The spleen was not palpable and there were no signs of fluid in the abdominal cavity. Other physical signs were negative.

The temperature ranged between 100.4 and 102.1 F. The first blood count was: Hb. 14 gm.; r.b.c. 3,840,000; w.b.c. 16,000 per cu. mm.; polymorphonclears 96 per cent. Of the latter 26 per cent were segmented and 70 per cent were stab forms. Lymphocytes

were 2 per cent; monocytes 2 per cent. There were no eosinophiles.

A diagnosis of acute suppurative cholecystitis with secondary hepatitis was made and a laparotomy performed. A normal gall bladder and spleen were found, but the right lobe of the liver had a nut-meg appearance and contained an abscess. Aspiration of the latter yielded 10 ounces of a thick, creamy, slightly brownish pus. A catheter was introduced and sutured in place.

Examination of the pus revealed Endameba histolytica and culture revealed *Bacillus coli*.

Two days later symptoms subsided and the temperature became normal; within seven days the catheter draining the abscess was removed; the wound healed and convalescence was uneventful. Amebicidal therapy was instituted upon the patient's return to the medical ward and he was discharged clinically cured, November 21, 1935. Before the patient's discharge, ten stool examinations and duodenal drainages were negative for ameba and cysts. Proctoscopic examination showed no evidence of ulceration, but the X-ray appearance of the colon was suggestive of some inflammatory process involving the cecum.

Accompanying the author's report there is a short review of the literature contrasting the geographical incidence of amebiasis. Craig states that 5-10 per cent of the American population harbor this infestation, while in Philadelphia at the Jefferson Hospital during the last decade there was one case among approximately 120,000 admissions and 3,000 autopsies, and at The Philadelphia General Hospital among approximately 232,000 admissions and 24,000 autopsies there were five proven cases.

It must be remembered that in a high percentage of cases the first symptoms of amebiasis may be an abscess of the liver, and the time elapsing between the infestation and the appearance of the liver abscess may vary from a few months to many years. In the absence of a history of amebic dysentery the primary lesions, in the majority of instances, can be located in the cecum and ascending colon, which would produce no diarrhea.

The medical and surgical therapy is briefly discussed.

KUHLMANN, FRITZ.

(The Radiology of Diseases of the Small Intestine). Dünndarmstörungen im Röntgenbild. Fortschritte auf dem Gebiete der Rontgenstrahlen, 54:5:433, Nov., 1936.

Disturbances of the small bowel generally play only a small part in respect to practical diagnosis. The chief factors of diagnosis of small bowel conditions are the history, palpation, especially the determination of points of tenderness, investigation of the feces and X-ray investigation. Investigation of the feces in the majority of cases gives no definite results as, during the passage of the feces, via the colon, changes which originated in the small bowel become masked. The essential means of diagnosis, apart from the history, is the radiological investigation of the small bowel.

Before information can be derived concerning pathological conditions, the appearances of the normal small bowel must be known. The author deals with the superimposition of the small bowel contents in a surface projection and the effect of excessive secretion which can give rise to loss of definition of roentgenograms.

Disturbances of the small bowel can

be recognized as defects of motility, an acceleration of the passage of contents, obstruction of the passage of contents and defects of tonus, namely hypertonus and atony (diffuse and localized), hypersecretion and lack of response to the stimulation of the barium meal. In other small bowel disturbances there is abnormal development of flatus, which is particularly described in respect to the ileum. Mucosal relief investigations in disease of the small bowel are of little value owing to the great complication of the normal relief appearances. In inflammatory conditions there are disturbances of the appearances owing to the long continued non-movement of the mucous membrane when inflammatory swelling is present.

After describing the general symptome of disease of the small bowel, particularly chronic enteritis, the various subsidary types of the disease are dealt with. The types of pain experienced by the patient are compared as to type, degree, localization and the period of their occurrance in relation to the radiological findings.

SCHEIBEL, OVE.

Concerning Pitressin in Roentgen Examination of the Abdomen as an Agent for Reducing Shadows Caused by Intestinal Gas. Acta Radiologica, 17:511, Oct. 31, 1936.

Aside from true ileus in which the amount of gas in the intestine and the distribution thereof are of great importance in roentgen diagnosis, it is mainly in the X-ray study of the urinary passages that one finds large amounts of gas in the intestine interfering with the roentgen-ray study. Particularly in renal colic gas may be present in such quantities that it resembles ileus, or rather reflex ileus, which can be taken for true ileus. At the Bispebjerg Hospital attempts have been made to reduce intestinal gas content by various dietary measures, such as laxatives, enemas of various kinds, an esophageal tube passed into the stomach to prevent swallowing of air, etc. Finally experiments were done with pitressin, a constitutent of pituitrin, carried out in patients in whom intestinal gas accumulations caused inconvenient shadows.

The gas content of the intestine depends on whether the patient is recumbent or erect. It is explained that in the recumbent position the patients swallow more air than when erect, and that in this position the passage of air down the intestine is not hindered by the "water-trap" at the pylorus as it is when the patient is erect. This is the reason one finds more flatus on the second post-operative day than on the first.

The author found the effect of pitressin was ideal in 13 out of 15 cases. In 3 of these cases it was necessary to administer the 10 units in a single dose, one-half hour before the examination in order to get the desired effect, which was obtained only upon a third examination. With the injection of 10 units of pitressin the patients complained of temporary but fairly marked gastric pain, and they became somewhat pale. Their pulse rate was not affected. Repeated observations have failed to show any marked rise in blood pressure. It is recognized that this is contrary to the reports from another source.

In spite of the inconvenience that a single dose of 10 units gives the patient, the author maintains that the advantages offered by his method justifies one giving it preference.

Investigations of the effect of pitressin on the colon after injection of the contrast enema shows no perceptible change in the position or dimentions of the colon. In the colon after being filled with residues from an opaque repast taken 24 hours before, the contrast substance after the injection of pitressin is seen to have been moved in an anal direction.

Special success has been found in gall bladder roentgenography, the intestinal gas being freed from the gall bladder

℞ TAUROCOL

For Lagging Biliary Function

Taurocol is a combination of bile salts, extract of cascara sagrada, phenolphthalein and aromatics. Its action is to stimulate the flow of bile without irritation to the liver or the gastro-intestinal tract and to act as a laxative or a cathartic. Recognized and widely prescribed by the medical profession for over a quarter of a century.

Other Plessner Products: Taurocol Compound with digestive ferments, Neo-Taurocol without phenolphthalein and Vera Perles of Sandalwood Compound.

THE PAUL PLESSNER COMPANY
DETROIT, MICHIGAN

region in the majority of cases. No contraction of the gall bladder was noted after the use of 10 units of pitressin given intramuscularly in one dose.

The study showed that with pitressin injection gas is far less likely to complicate the roentgen examination than without its administration.

EMERY, E. S., JR.

The Use of Adsorbents in Gastro-Intestinal Disease. J. A. M. A., Vol. 108, p. 202, Jan. 19, 1937.

Adsorption may be defined as the attachment of one substance to the surface of another. Usually the substances are of a colloidal nature with large sized molecules. It is a complicated subject and the therapeutic action of them in the gastro-intestinal tract cannot always be predicted by the laboratory.

Clinically only charcoal and kaolin have been used because of their adsorptive properties. Charcoal has an excellent affinity for gases when dry, and will also adsorb various organic acids and drugs. Recently, activated charcoal, that is heated to a certain temperature, has been recommended because of a higher adsorptive capacity.

Kaolin, a mixture of aluminum silicate and other substances, has been used in China for centuries in the treatment of summer diarrheas and cholera. The action of kaolin is not exactly known, but Fautus believes that it changes the intestinal flora from a proteolytic to an aciduric one over a period of from ten to thirty days.

However, the use of these substances is limited because of their amphoteric qualities, because of the danger of forming plugs which may cause partial or complete bowel obstruction, or trauma to the intestinal wall.

Clinically, kaolin is indicated in patients suffering from severe food poisoning and dysentery. It is not indicated in those diarrheas due to nervousness, fat intolerance, exophthalmic goitre, pernicious anemia, or amebic dysentery. It seems that it is contraindicated in the treatment of idiapathic ulcerative colitis because the large amount necessary to produce results would interefer with adsorption in the rest of the tract. It is also contraindicated in diverticulitis, the dyspepsias and autointoxication.

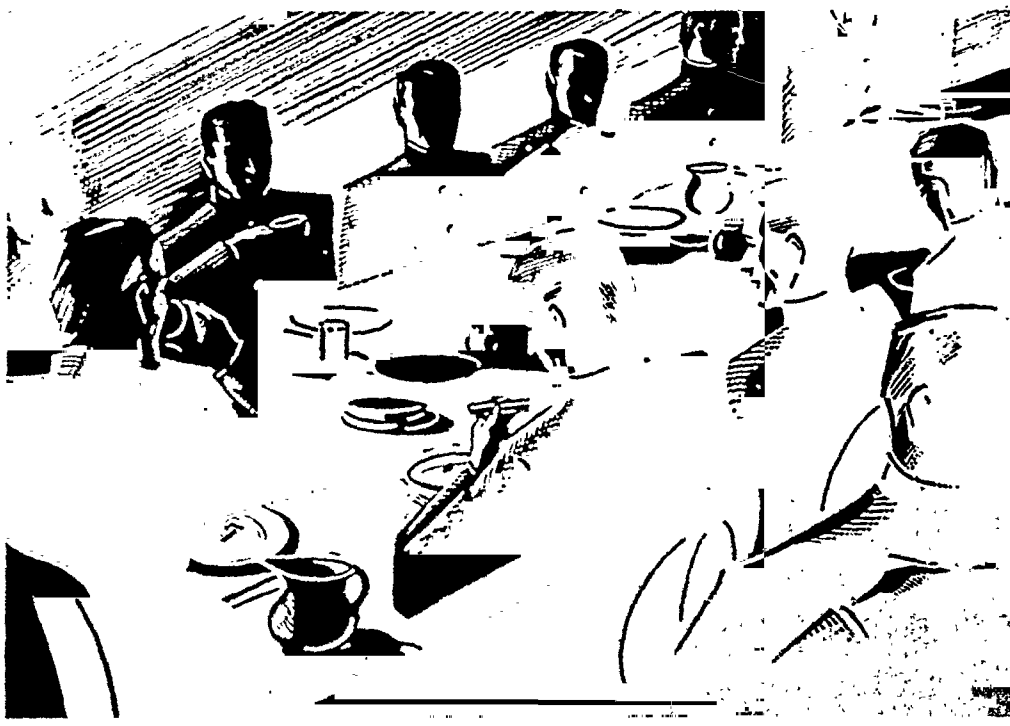
JOHNSON, SYDNEY E.

The Frequency of Air Under the Diaphragm in Perforated Gastric and Duodenal Ulcer. J. A. M. A., 108:295, Jan. 23, 1937.

The finding of air under the diaphragm has long been known to be an important point in the diagnosis of perforated peptic ulcer. The exact frequency of the finding has not, however, been demonstrated. In an analysis of forty-two cases of proved perforated peptic ulcer the author found that thirty-five or eighty-three per cent showed roentgenographic evidence of pneumoperitoneum. He also found it was important to do the roentgen examination as early as possible especially where there is a problem of differential diagnosis.



Francis D. Murphy, Milwaukee.

OCHSNER, ALTON AND STORK, AMBROSE H.

Mechanical Decompression of the Small Intestine in Ileus. J. A. M. A., 108:260, Jan. 23, 1937.

The "stripping" or "milking" out of the contents of the intestine in those cases where distention is so severe that replacement of the bowel within the abdominal cavity is very difficult has been used enthusiastically by some men; others are not in favor of it. The present report is an analysis by the author of sixteen clinical cases of intestinal obstruction operated on between the years 1928 to 1931, before the introduction of the Wangensteen method of drainage. After studying these cases the author believes that stripping of the intestine should seldom if ever be done. He has observed that postoperatively there is a fall in blood pressure, an impairment of intestinal

DIET

Proper diet is an aid to regular elimination and where constipation is present, diet is a factor that must be considered. Petrolagar-Plain, because it performs only a lubricating and softening function, is also an aid to regular elimination. It is useful as an adjunct to diet because it permeates hard impacted masses and produces soft easily passed stools. Petrolagar is prepared in five types. . . . Plain, Unsweetened, with Phenolphthalein, with Milk of Magnesia and with Cascara, providing a choice of treatment adaptable to the individual patient. Petrolagar Laboratories, Inc., Chicago.

Petrolagar is a mechanical emulsion of pure liquid petrolatum (65% by volume) and agar-agar. Accepted by the Council on Pharmacy and Chemistry of the American Medical Association for the treatment of constipation.

Petrolagar

activity and muscular tone. Even when done very carefully there is considerable trauma and shock resulting from the procedure, subserous hemorrhages being observed in some of the cases.

Proper preoperative preparation such as the replacement of electrolytes, administration of heat to the abdomen, liberal doses of morphine and the employment of an indwelling gastric catheter attached to a suction apparatus will in most cases relieve the distention. Even if these procedures do not relieve the distention the untoward effects following stripping are so severe that patients get along just as well without as with it.

Francis D. Murphy, Milwaukee.

HARKINS, H. N.

Mesenteric Vascular Occlusion of Arterial and of Venous Origin. Arch. of Path., 22:5, 637, Nov., 1936.

The author reviews the literature on abdominal vascular occlusion under four headings and analyzes nine cases mainly from the standpoint of "secondary shock" as the actual or contributing cause of death. "Secondary shock" is defined as the syndrome due to the loss of large amounts of plasma-like fluid or blood from the circulating blood stream. Clinically the occlusions were divided into four types: (1) thrombosis of the portal vein, due either to pylethrombophlebitis or to ordinary thrombosis; (2) occlusion of the mesenteric vein, usually due to thrombosis and often associated with thrombosis of the portal vein; (3) occlusion of the mesenteric artery, often embolic in origin, and (4) intestinal strangulation, in which often both veins and arteries are occluded.

Of the nine cases reported eight patients died and came to autopsy and one patient, a boy aged sixteen, lived after a resection of four feet of small intestine. Three cases were of the venous type and six were of arterial origin. Two of the latter cases presented no infarction of the intestine, explained on the assumption that a large collateral circulation existed in each. In the remaining six cases extensive hemorrhagic extravasation into the bowel occurred and much free fluid was found in the peritoneal cavity; so great a loss of circulating blood plasma that the author considered it an important, at least contributing, cause of death. Arterial occlusion was more frequent than venous. Most of the patients were in the upper middle age group and most of them had a pre-existing cardiovascular disease. In all an exaggerated symptom of pain, out of proportion to objective signs in the abdomen, was noted.

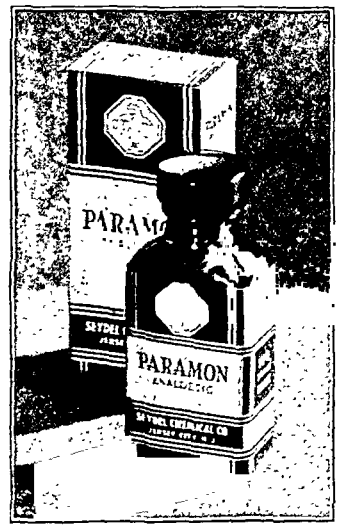
LOEFFLER, L.



Genesis of Intestinal Infarction Following Embolization of the Superior Mesenteric Artery. Arch. of Path., 22:6, 755, Dec., 1936.

The author ligated the superior mesenteric artery and the portal vein in rats and studied their immediate effects under the microscope with low magnification in order to throw light, if possible, on the presence of hemorrhagic infarction of the small intestine after embolic occlusion of the superior mesenteric artery in man. The latter occurs, as evidenced by autopsy findings, whereas one would expect that occlusion of the artery would result in anemic necrosis of the gut.

The author found that if the animal lived a few hours after experimental ligation of the superior mesenteric artery simple anemic necrosis resulted. The gut became softened, contracted and empty, some imbibition took place, and small hemorrhages with congested capillaries were seen, but hemorrhagic infarction was not present. After ligation of the portal vein the intestine was dark red, suffused with numerous hemorrhages, was dilated and filled with bloody mucoid material. The ex-

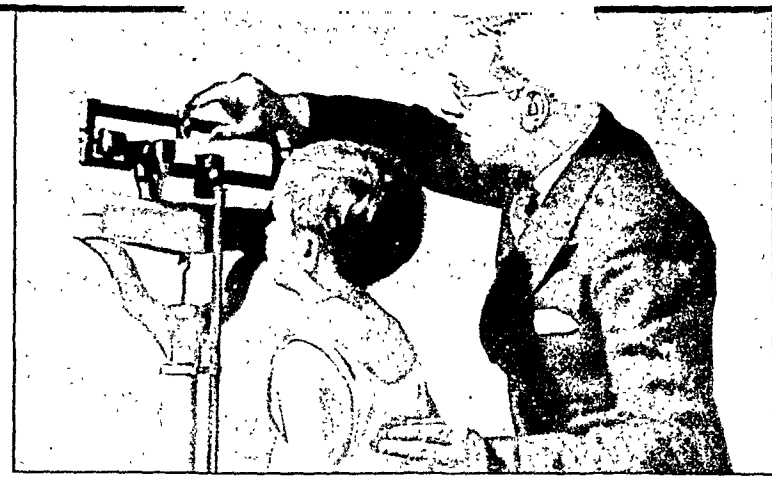
A Non-Toxic Analgesic

PARAMON

The advantage of a non-toxic analgesic in treating a localized pain is as important as treating the systemic condition.

When Salicylates have been used in Arthritis and are discontinued, PARAMON, for the pain of the transition period is indicated.

The successful results of PARAMON are due to its simultaneous sedative action on the central nerve system and in the interruption of nerve impulses. It may be administered in as large a dose as may be found necessary to give relief.



Write to us today for information about these new and useful products.

SUBENON

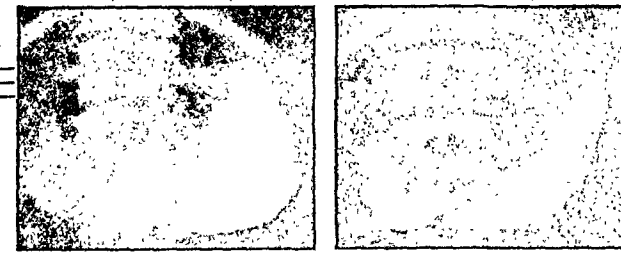
When Children Are UNDERWEIGHT

Faulty nutrition and lack of appetite are frequent causes of underweight. The addition of a special food supplement to the ordinary diet often brings desired results

OVALTINE is the kind of food supplement of special value for undernourished children. It furnishes special nutritional properties in a form which children welcome. It contributes to weight gains in several ways:

First—It helps restore normal appetite, not merely by tempting the taste, but also by helping to stimulate the lagging appetite. It contains 57 International units of the appetite-promoting vitamin B per ounce. And in addition, it causes the stomach to empty starchy foods more rapidly, which allows hunger to return sooner. (See X-rays below.)

Second—Ovaltine itself is easily digested. It not only aids the digestion of starchy foods but in addition it increases the digestibility of milk.



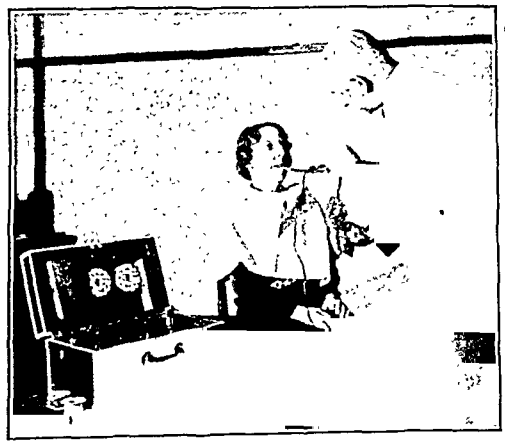
Third—This food-drink supplements the diet with nourishing and protective food elements—proteins, carbohydrates, minerals and vitamins—all important factors for proper growth.

Ovaltine combines maximum nourishment with minimum bulk in a form readily taken. Thus underweight children often respond quickly when it is added to the ordinary diet at meals and between meals.

Why not recommend Ovaltine for some undernourished child under your care? We will send you a large can of Ovaltine prepaid for this purpose. Address The Wander Company, 360 North Michigan Avenue, Chicago, Illinois, Dept. D.N.6

Copr. The Wander Co., 1937

(Without Ovaltine) (With Ovaltine)



● *The x-ray reproductions show the stomach 2 hours after a starch meal was taken, without and with Ovaltine. The average decrease in gastric contents due to Ovaltine was 20%.*

periments supported his belief that collateral circulation was not responsible for the presence or absence of changes in the tissues unless such channels are present in "excessive" numbers. Microscopically, it was found in vivo that the cause of hemorrhagic infarction is neither venous reflux or arterial reflux nor collateral circulation. In man anemic necrosis of the bowel does not occur after embolism, but an infarction analagous to a pulmonary infarct occurs because circulation with which one deals in embolism is not a normal but a failing circulation which predisposes to stasis and hemorrhage. The cause of the hemorrhagic infarction is not to be sought in the region of the infarct but in the congested and altered state of the circulatory channels. It seems fundamental that there is a difference between the experimental results and the findings observed clinically; that this difference is due to markedly increased venous pressure and that this condition of passive congestion actually exists in the intestinal circulation at the time embolism occurs.

N. W. Jones, Portland.

A STOMACH CAMERA

Photographing the stomach

The use of the gastric camera is similar to the use of an ordinary stomach tube. The entire procedure takes less than a minute.

ACTUAL PHOTOGRAPHS of the interior of the stomach are obtained by means of this ingenious instrument. A valuable aid in the diagnosis of gastric lesions.

May we send you literature and gastrophotographs?

ROSENKRANZ, K. AND HOWARD, L. D.

Tubular Tuberculosis of the Liver. Arch. of Path., 22:6, 743, Dec., 1936.

The authors present three typical cases of tuberculosis of the intrahepatic bile ducts, so-called tubular tuberculosis of the liver. Two occurred in young male Filipinos and one in a young white woman. All three suffered from generalized tuberculosis. The authors conclude that two factors are necessary for the origin and extension of tuberculous cholangeitis. The first is an early lymphatic and hematogenous generalized spread of the primary infection before resistance has been established. The second is an intestinal site for the primary infection and extensive caseation of the mesenteric glands. Caseous tubercles then develop in the periportal tissue and rupture into the bile ducts. The bile ducts themselves are not primarily infected. This type of tuberculosis is usually found in young children and in races that do not have high resistance against infection.

BRUES, A. M., DRURY, D. R. AND BRUES, M. C.

A Quantitative Study of Cell Growth in Regenerating Liver. Arch. of Path., 22:5, 658, Nov., 1936.

The author studied the rate of growth of liver tissue both as regards mass and the increase in cell number during the process of regeneration following partial hepatectomy in the albino rat. It had been shown previously by Adolph in case of cultures of paramecium that these two elements of growth varied independently of each other with variation of temperature.

Forty animals on a bread and milk diet were studied at different periods of time under as nearly controlled conditions as possible. Six animals were kept on a high carbohydrate diet for a week before operation, eleven on a high protein diet, thirteen on a high fat diet, and four were starved for four days previous to operation, at which time about 70 per cent of the liver was removed. The result of the study showed that the mass of the residual liver fragment increased over 50 per cent in the first twenty-four hours after operation and over 100 per cent in the first forty-eight hours. A secondary increase occurred after six days incident to the regaining of weight lost postoperatively. The number of cells in the fragment, however, showed no significant increase in the first twenty-four hours, but later they increased in number about as the mass increased, except that there was no secondary increase after several days. In starved animals mass increased less than in fed animals, but the cell number increase was about

Promoting

INTESTINAL FUNCTION

Stamyl contains the protein, starch and fat splitting pancreatic enzymes in a highly concentrated, stable and standardized form. Another constituent is hemicellulase, an enzyme which disintegrates cellulose of vegetables and fruits, and hence aids in their digestion.

Stamyl is particularly useful in defective intestinal digestion as manifested by flatulence, discomfort after meals, anorexia, diarrhea or constipation.

DOSE: 1 tablet, three times daily, immediately after meals. In severe and obstinate cases the dose may be increased. The patient should be advised not to chew the tablets.

HOW SUPPLIED: Bottles of 25 enteric coated tablets.

TRI-CALSATE

the BUFFERED NEUTRAL ANTACID

Tri-Calsate is a powerful neutralizer of gastric HCl . . . yet does not cause a rebound in acidity or alkalize the stomach contents. The buffering effect of its end salts protects against a harmful alkalosis.

As no carbon dioxide is evolved during the reaction in the stomach, the distress from gastric distention and belching is eliminated.

Tri-Calsate is non-toxic and non-irritating. The probability of gastro-intestinal irritation is remote . . . the kidneys are unharmed. Patients like it because it is palatable and easy to take.

Available on prescription at your pharmacy or direct in 4 oz. and 18 oz. bottles

Avoid The Vicious Circle of Alkali Neutralization

Write for trial package and complete literature.

the same. High carbohydrate and high protein diets showed less increase in liver mass than a normal diet, but the cell increase was not much affected. A high fat diet cut down the cell increase markedly, much more than did starvation. The normal nitrogen content of the fasting rat livers in the series was 3.5 per cent. The tissue added the first day contained 1.4 per cent. From then on the restored liver rapidly approached normal liver in nitrogen content.

In general it was found that the rate of restoration of liver tissue was markedly affected by diet, but the increase of cells in number was less dependent both on diet and on growth in mass of the tissue.

FOUCAR, F. H.

Syphilis of the Gastro-Intestinal Tract. Report of a Case of Gumma of Transverse Colon with Review of the Literature. Amer. Jour. Path., XIII:1, 65, Jan., 1937.

A case of syphilis of the transverse colon in a male, aged 32 years, is reported, in which treponema pallida were demonstrated in the tissues. During life the patient had given repeated negative Wassermann blood reactions, but + to +++ Kahn tests. Insufficient antisyphilitic treatment had been administered. In March, 1934, his appendix was removed because of pain in the right lower abdomen. In October, 1936, he presented a movable tumor mass in the right abdomen and suffered colicky attacks of watery diarrhea without melena and dull abdominal pain with loss of weight and strength. A roentgen ray diagnosis of annular carcinoma of the transverse colon near the hepatic flexure was made.

Twelve cases of acquired syphilis of the intestine, including the author's are reviewed. Their ages averaged 44 years. Eight were males and 4 females. The Wassermann reaction was negative in one-half of the cases. The lesions were single in 8 and multiple in 4. The jejunum was involved 6 times, the ileum 2 and the large intestine 4 times. None of the cases were correctly diagnosed. Nine were diagnosed preoperatively as carcinoma, one as cholecystitis and one as intussusception. One patient died of generalized peritonitis following perforation of a syphilitic jejunal ulcer. Suggestive roentgen ray evidence of intestinal syphilis is that obstruction is usually in the small bowel and there may be multiple lesions present. When in the colon the lesion is more frequently away from the flexures, whereas carcinoma is apt to involve them.

N. W. Jones, Portland.

FOOT, N. C.

The Identification of Tumor Cells in Sediments of Serous Effusions. Am. Jour. Path., XIII:1, 1, Jan., 1937.

The diagnostic value of reported cells in a given fluid for examination the author summarizes in the following manner:

1. The presence of fragments of tumor with the cells arranged in acini or papillae about a stroma that is definitely fibrovascular is positive evidence of primary or metastatic malignant tumor of the serous membrane in question.

2. A nucleolar-nuclear ratio (n/N ratio) above 0.25 is of undoubted value; one of 0.30 or more practically pathognomonic of the presence of tumor.

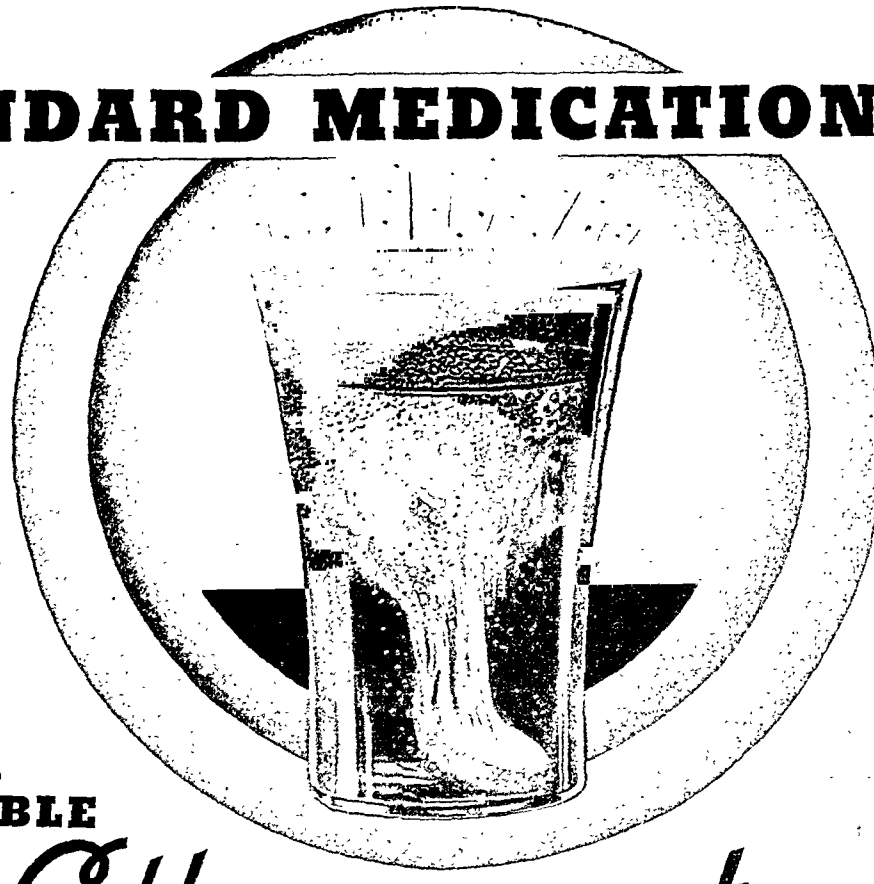
3. Mesothelial covering cells are most easily confused with tumor cells on account of their large size and prominent nucleus, but they are uniform and regular in size. Tumor cells show a wide variation in measurements and have a high n/N ratio.

4. Multinucleation and cell clumping is of no diagnostic value. Mitoses occur in cells in both sediments, but monster or abnormal mitoses are found only in tumor cells.

5. The presence of erythrocytes and fibrin is of little diagnostic significance.

N. W. Jones, Portland.

RESTORE
The Alkali Reserve
CAKNAM



Supplies the four bases, calcium, potassium, sodium and magnesium in true physiological proportions. Rich in citrates — entirely free from tartrates and sodium chloride. Granular effervescent. Available on prescription in 3½ oz. bottles.

STANDARD MEDICATION

IN A PALATABLE

Effervescent DRINK

An improved method of prescribing certain standard forms of medication is provided in the following effervescent tablets:

- **ASPIR-VESS**—Combines the valuable analgesic, antipyretic properties of aspirin with a systemic alkalizing effect (as sodium citrate) equivalent to 31 grs. of sodium bicarbonate and 21 grs. of citric acid.
- **BROMO-VESS**—The well known triad—bromides of sodium, potassium and ammonium in a palatable, alkaline, effervescent tablet. No salty taste.
- **CINSA-VESS**—A combination of cinchophen, sodium salicylate, colchicine. The final solution is definitely alkaline, which combats the associated acidotic condition usually encountered, and likewise increases tolerance.

PAIN

is your patient's first concern in peptic ulcer

Pain, usually the patient's only indication of peptic ulcer, is quickly and effectively held in abeyance with Creamalin, the distinctive colloidal cream of aluminum hydroxide. Through its profound acid-fixing qualities (12 vol. HCl in 30 min.), Creamalin produces constant anacidity of the gastric contents. Hyperperistalsis and pylorospasm are overcome, as well as acid irritation and digestion of the ulcer bed.

★ ★

Healing is remarkably rapid with Creamalin. Roentgenologic disappearance of the ulcer crater is demonstrable in 7 to 12 days with continuous drip administration through the Creamalin Automatic Drip Control, and in 3 to 6 weeks when Creamalin is given orally.

★ ★

Creamalin, since it is not absorbed systemically, produces no change in plasma CO_2 or pH, hence cannot produce alkalosis. It may therefore be given in *effective* dosage.

Comprehensive literature on Creamalin and the Creamalin Automatic Drip Control, together with sample, sent to physicians on request.

Creamalin
THE SUCCESSFUL ULCER TREATMENT

VIENNA TO HAVE INTERNATIONAL CONGRESS OF SHORT WAVE SPECIALISTS. DOCTORS D'ARSONVAL AND ZENNECK, AND SENATOR MARCONI ON COMMITTEE OF JULY CONGRESS.

From July 12th to 17th the scientific workers in one of the most rapidly advancing fields of physics, chemistry, biology and medicine will convene in congress in Vienna under the patronage of official Austria as represented by a committee including the Federal President, the Austrian Chancellor, the Rector of the celebrated University of Vienna, the Rector of the Vienna Technical College and the Mayor of the City of Vienna. The Congress sessions will be comprised of lectures by world famous scientists followed by brief readings given by members and general discussions. The papers read by members must not take more than fifteen minutes reading time. Those wishing to read papers are requested to file a special application. The languages admitted are English, German, French and Italian. The major papers read, as well as those presented by members will be printed in full and copies distributed to those attending the Congress provided applications are received in time. In conjunction with the Congress an exhibit showing the latest advances in the short wave field, both in the abstract field and the field of applied practice will remain open throughout the congress.

The subjects to be dealt with include: Physics, Biology, Chemistry and Medicine. In the field of Physics the subjects to be covered are: the properties of short waves and ultra short waves; generation, conduction, radiation and propagation; reflection refraction, absorption; measurement of SW and USW. Exploration of Heaviside-Appleton layers of the atmosphere. Chemistry and Physical Chemistry will be thoroughly explored in its relation to short wave work and the practical aspects of short wave application in the physical field will be treated extensively.

In Biology the action of short waves of various types on plants, animals, organisms, enzymes and ferments; heat effect and size particles; percutaneous SW diathermy; destruction of noxious insects; experiments will be included.

In the medical field, the connection of which with short wave therapy has aroused wide world interest, the following topics will receive attention: indications and counter indications for the therapeutical application of SW and USW. USW therapy, its application in cases of acute inflammations of bacterial genesis in internal medicine, surgery, gynecology, dermatology, opthalmology, otiatry and neurology; SW therapy in connection with acute infectious diseases, especially with polomyelitis acuta; sensibilization by SW of malign neoplasms refractory to X-rays; SW diathermy, its application in cases of chronic rheumatic diseases of joints and muscles; the technical side of apparatus.

All lectures and discussions will take place in the morning, leaving the afternoons free for demonstrations, experimental work or sight seeing tours. Membership fee of the congress is thirty Austrian Schillings which fee includes the cost of all printed reports. The fee is payable in the local currency to the official Austrian representatives abroad. A crowded calendar of social events including official receptions and merry excursions has been planned to supplement the serious work of the members of the congress.

Programs and application blanks will be furnished upon request by writing to Austrian State Tourist Department, 630 Fifth Ave., New York City.

The two following abstracts throw light on the vitamin value of canned foods:*

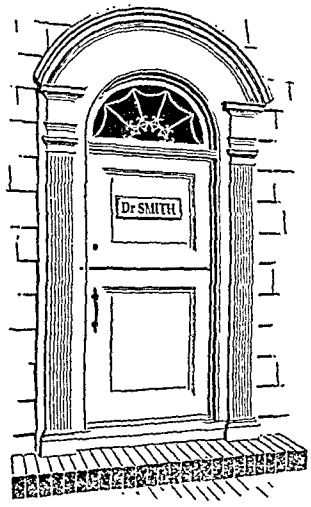
SEBRELL, W. H., WHEELER, G. A. AND HUNT, D. J.

The Blacktongue-Preventive Value of Seven Foodstuffs. U. S. Public Health Reports, 50, 1333, 1935.

These investigators consider canine blacktongue and human pellagra to be analogous conditions, hence the determination of the blacktongue-preventive value of a food is considered a measure of its pellagra-preventive value.

Forty per cent of the total calories in an otherwise blacktongue producing diet were supplied by a commercial brand of canned chicken. Four dogs were kept for a year on this diet without the appearance of any symptoms of blacktongue, indicating that commercially canned chicken is a valuable source of the pellagra-preventive factor.

GOLDBERGER, JOSEPH, WHEELER, G. A. AND ROGERS, L. M.



A Study of the Blacktongue-Preventive Value of Lard, Salt Pork, Dried Green Peas, and Canned Haddock. U. S. Public Health Reports, 45, 1297, 1930.

Blacktongue in dogs and pellagra in the human are analogous conditions, in the opinion of the authors; and the success or failure of a diet in preventing blacktongue is a satisfactory basis for the evaluation of its pellagra-preventive values.

Canned haddock, a moderately priced canned food, fed as a relatively large proportion of the diet, prevented the appearance of blacktongue in dogs. Canned haddock might well be included in the diet for the control or prevention of pellagra in rural areas of the South.

*These abstracts were furnished by the Research Department of the American Can Company. *Editor.*

INFANT FEEDING PRACTICE

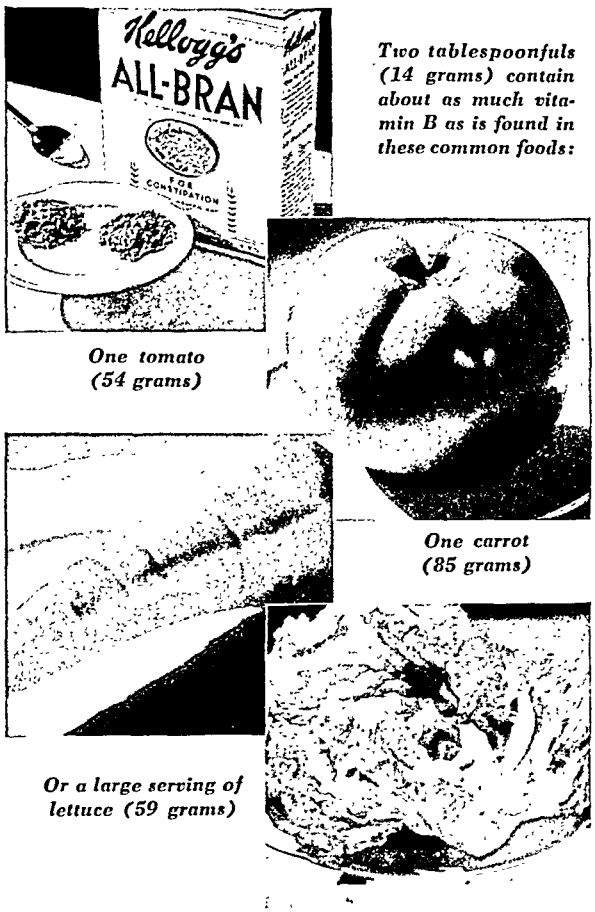
should be in the private doctor's office

IMPROVED economic conditions are returning babies to private practice. Encourage it.

The doctor knows his practice, the mother her economies. When the infant feeding materials prescribed are within the reach of every budget, mothers will appreciate the physician and babies will thrive.

Karo is a most economical milk-modifier. It consists of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor) and is suitable for every formula.

A tablespoon of Karo gives twice the number of calories (60) in comparison with a tablespoon of any powdered maltose-dextrins-dextrose, including Karo powdered. Karo is well tolerated, highly digestible, not readily fermentable and effectively utilized by infants.



For further information, write

CORN PRODUCTS SALES COMPANY
Dept. DN-6, 17 Battery Place, New York, N. Y.

★**Infant feeding practice is primarily the concern of the physician, therefore, Karo for infant feeding is advertised to the Medical Profession exclusively.**

Kellogg's ALL-BRAN ... a good source of the important vitamin B

Two tablespoonfuls (14 grams) contain about as much vitamin B as is found in these common foods:

One tomato (54 grams)

One carrot (85 grams)

Or a large serving of lettuce (59 grams)

NUTRITIONAL authorities recognize the importance of vitamin B in helping to maintain muscular tone in the intestines.

Kellogg's ALL-BRAN contributes a fair share of the vitamin B needed daily. This cereal also supplies iron for the blood and corrective "bulk." Within the body, ALL-BRAN absorbs twice its weight in water, and cleanses the system.

This natural laxative food may be served as a cereal with milk or cream, or cooked into recipes. Sold by all grocers. Made by Kellogg in Battle Creek.

NOTICE

"We call attention to the direct-mail campaign of The Wander Company. This consists of a series of mailings of four-page pamphlets describing the results of research on Ovaltine. The first of this series deals with the effect of Ovaltine on the digestion of starches and the influence which this property exerts on gastric emptying time. The tone of the bulletin is dignified and conservative both in typography and copy. This type of promotion should be well received by the profession.

Fifth International Congress of Radiology to convene in Washington, D. C.

One of the most outstanding scientific events ever held in the United States has been set for Chicago this September, when the Fifth International Congress of Radiology convenes. It will be the first time that the world leaders in the medical and scientific development field of X-ray and radium have met in America, according to Dr. Arthur C. Christie, Washington, D. C., president of the Congress. The dates are September 13 to 17, inclusive, and the meeting place is the Palmer House.

At least 500 distinguished delegates and guests from a score of European countries as well as physicians from Mexico, Canada and Central and South America are expected to attend, with more than 2,000 other delegates and visitors from all parts of the United States.

The annual medical conventions of the leading radiological bodies of this country will be merged with the international congress. These include the American Roentgen society, the American College of Radiology, the Radiological Society of North America and the American Radium society.

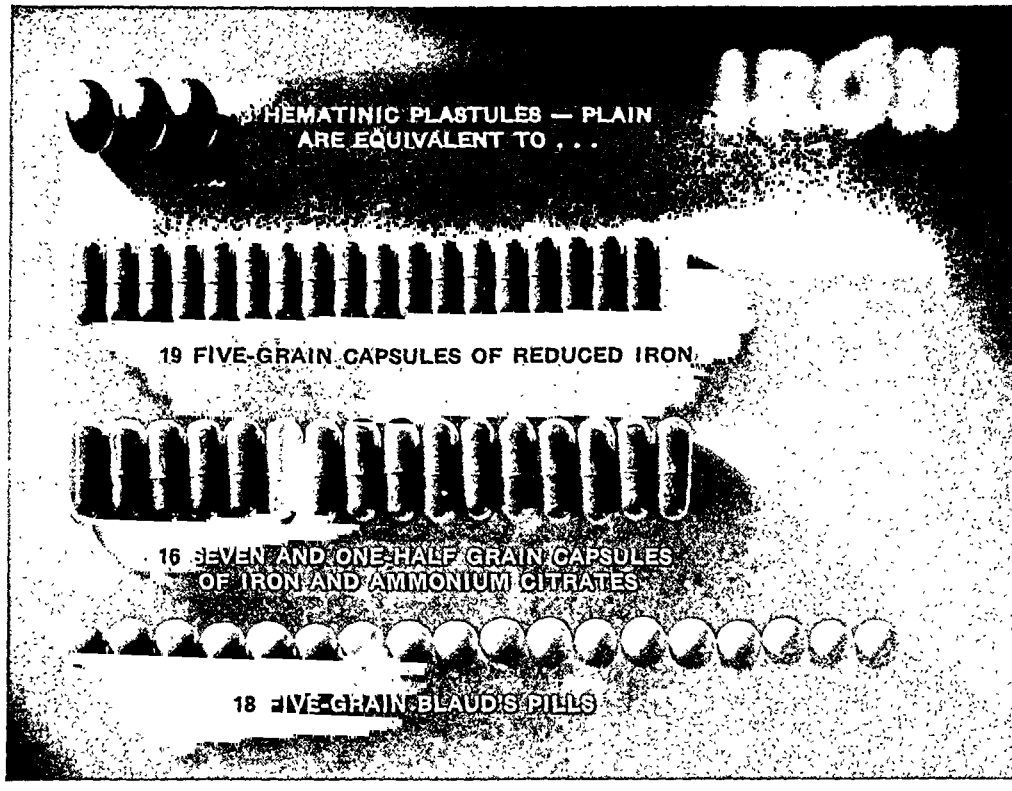
The first International Congress of Radiology convened in London in 1925. Meetings are held every three years. The physicians and physicists met in Stockholm in 1928, in Paris in 1931 (where they paid tribute to the then living Madame Curie, co-discoverer of radium) and in Zurich in 1934.

COOK COUNTY GRADUATE SCHOOL OF MEDICINE

In affiliation with COOK COUNTY HOSPITAL

Announces

Twenty Hour Course in Gastroscopy



By Professor Rudolf Schindler

The course will consist of practical work in the use of the flexible gastroscope designed by Dr. Schindler, formerly of Munich, Germany. Gastroscopic examinations will be made daily, and during the second week gastroscopies will be carried out by each student. The clinical, x-ray and gastroscopic findings will be compared.

The course will occupy two hours daily from Monday to Friday for two weeks. Courses are offered on July 5-17 and August 2-14. Minimum attendance 2—Maximum attendance 4.

From July 19th to July 31st, Dr. Aaron Arkin and Dr. Rudolf Schindler will offer a forty hour course in Gastro-Enterology and Gastroscopy.

For further information address the Registrar, 427 South Honore St., Chicago, Illinois.

HEMATINIC PLASTULES

IMPROVED IRON MEDICATION

Large doses of iron are no longer necessary for the successful treatment of hypochromic anemia. Independent investigations have proved that Hematinic Plastules yield rapid clinical response, equivalent to the results obtained from massive doses of other forms of iron • The average patient requires only three Hematinic Plastules Plain daily which obviates the unpleasant effects usually associated with massive iron feedings • We will be pleased to send samples and literature on request.

BILE SALTS

Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

Leaders in other branches of medicine will participate in the Congress too as Dr. Christie points out that "The Unity of Medicine" will be the theme of the entire Congress.

"These international congresses seek to maintain a continuity of program over the years, and in consequence such vital subjects to the radiologist (and to the general public) as diagnosis and treatment of cancer and many other diseases and teaching and training in radiology will be on the agenda of this congress as well as at former meetings.

"Radiology is an important branch of medicine, and is indeed part of the entire tree, and not merely a specialty as it was once regarded," added Dr. Christie.

More than 250 scientific papers will be read at the five-day meeting. These will be delivered in each lecturer's own language and will be automatically flashed on screens in English, German and French as the papers are read.

What will probably be the greatest scientific and technical exhibit in the history of a radiological congress will be assembled by physicians, physicists and manufacturers of such equipment in conjunction with the congress.

The general secretary of the congress, Dr. Benjamin H. Orndoff, is in charge of headquarters at 2561 North Clark street, Chicago, Ill. Honorary vice-presidents are Dr. George E. Pfahler of Philadelphia, Dr. James Ewing of New York and Dr. William D. Coolidge of Schenectady, N. Y. On the International Executive Committee are Dr. Arthur C. Christie of Washington, D. C., chairman; Dr. C. Thurstan Holland of Liverpool, Dr. Gosta Forssell of Stockholm, Dr. Antoine Beclere of Paris, Dr. Hans R. Schinz of Zurich, Dr. Karl Frik of Berlin, Dr. Mario Ponzio of Turin, Italy; Dr. Tamotsu Watanabe of Osaka, Japan; Dr. Heliodoro Tellez-Plasencia of Santander, Spain, and Dr. Gottwald Schwarz of Vienna.

From: Secretary's Office, International Congress, 2561 N. Clark Street, Chicago, Ill., U. S. A.

"CONNOTATIONS"

By
H. J. SIMMS, M.D.
DENVER, COLORADO

The occurrence of more than one gall bladder in the human body was probably first described in medical literature by Plasius, in 1674. Pliny makes mention that on the day of Emperor Augustus' naval victory at Actium (31 B. C.), a double gall bladder was found in the sacrificial victim.

Galen (131-201 A. D.) believed the function of the pancreas was to act as a cushion for the stomach. Malpighi (1628-1694) described the structure of this organ. The histology was not described until 1869, and then by Langerhans. Its main duct was recognized by Wirsung in 1642.

The relation of the pancreatic juice to digestion was first noted by Bernard, in 1856. Corvisart, in 1857, and Kuhne, in 1867, observed the effect of the pancreatic juice on carbohydrates, fats, and proteins.

A cervical rib was first described by Humauld, in 1742, and Coote, in 1861, resected such a rib.

Kuster, in 1883, first recommended the ideal operation of cystotomy. McRidity in America one year later advocated the same procedure.

Gelatinized Milk

SCORES IN

INFANT FEEDING TESTS

A preliminary study conducted in the Department of Pediatrics of a prominent Eastern University was made with three groups of infants (fifty babies in each). The study was intended to duplicate the usual type case as seen by the practicing physician such as vomiting, constipation, and other disorders relating to the digestive system.

To determine any differences between cow's milk, lactic acid milk, and gelatinized milk* was the purpose. The results as reported (Archives of Pediatrics January-February 1937) are:

1. Infants fed gelatinized milk appeared to be less susceptible to infections, especially upper respiratory infections, than those fed acidified or cow's milk.
2. The occurrence of diarrhea was less frequent in the gelatinized milk group and acidified milk group than in the plain milk group.
3. The group of infants fed gelatinized milk had a better rate of gain than those groups fed acidified milk or plain cow's milk.
4. Vomiting and "appetite poor" symptoms among the infants were obviated or showed improvements when fed gelatinized milk in contrast to the feeding results of the other groups which showed little change.
5. The infants in the gelatinized milk group had more favorable results than the acidified milk group or cow's milk group in relation to constipation.

* One or two per cent of Knox Gelatine was added to the formula water which had been boiled and cooled. The gelatine was softened ten minutes before being added to the milk of the formula.

TESTAGAR

Effective In

Functional Chronic Constipation

- Bulky
- Lubricating
- Non-Irritating

TESTAGAR is a compound of the husks of Plantago Loeflingii Linn combined with the finest quality Agar-Agar. Especially valuable in treating atonic constipation as it produces a soft, formed, jelly-like fecal mass — smooth and non-irritating.

Samples will be sent for clinical test on request.

The TESTAGAR LABORATORIES, Inc.
424 W. Elizabeth St. Detroit, Michigan

Proven

CHOLERETIC *and* **CHOLAGOGUE**

EXICOL

Authorities agree that choleretics, whether bile salts or bile acids, are not cholagogues (they do not stimulate gall bladder evacuation). The effective and proven cholagogues are fats and fatty acids.***

containing both a fatty acid (oleic acid) and bile salts, is a true *cholagogue and choleretic.*

Furthermore ... it was definitely proven that the addition of oleic acid to bile salts (Exicol) increases bile secretion from the liver 100 to 200%.***

EXICOL fulfills the necessary requirements for the adequate management of diseases of the biliary tract.

Dose: 2 capsules t.i.d. a.c. Prescribed in boxes of 36 and 100.

BROOKLYN SCIENTIFIC PRODUCTS CO., INC.
70 Fifth Avenue, New York, N. Y.

Sampson, in 1725, recognized the distinction between obstructive and hemolytic jaundice.

Cholesterol gall stones are peculiar to man, however, biliary concretions known as ambergris occur in whales. These calculi are composed chiefly of cholesterol and are said to weigh as much as one hundred pounds.

Eller, in 1764, believed ganglia or synovial cysts resulted from rupture of the tendon sheath and extravasation of the synovial fluid into the tissues. Further opinion was suppressed until Gasselin, in 1852, suggested they developed from crypts in the synovial membrane.

Casper, in 1850, first mentioned the possibility of death from the delayed action of chloroform.

Nothnagel, in 1866, produced evidence that chloroform might produce fatty changes in the liver, heart and kidneys. Rosenbaum, in 1882, showed the liver to be poor in glycogen following administration of chloroform.

Fidel Pages, a young Spanish surgeon, perfected the technique of epidural anesthesia. He died from pneumonia a few days before his article appeared in literature. Dogliotti, in 1931, described the same technique before the Italian Surgical Congress though unaware of Pages previous report.

Congenital idiopathic cysts of the common bile duct was recognized by Vater, in 1723.

The first authentic case of gall bladder disease in a child was published by Gibson in 1722.

Von Neusser, in 1908, commented on the necessity of differentiation between pain of cardiac origin from the syndrome of pulmonary embolization. Hamburger and Saphir and more recently Averbuch have confirmed at autopsy that death presumably from coronary thrombosis is often due to pulmonary emboli.

Trendelenburg early observed the posture which he described was not free from circulatory embarassment during operative procedures. He advised against this position in plethoric individuals.

Cholesterol was first isolated by Conradi in 1775. It was analyzed by Chaureul in 1815. Flint, in 1862, believed the liver removed cholesterol from the blood and that hypercholesteremia depended upon pathologic changes in the liver.

Laborde, in 1874, injected irritants into the gall bladder of animals to determine whether painful stimuli were transmitted through the splanchnics.

Slipping ribs or recurring luxation of the lower costal cartilages with its associated symptoms was first described by Davis-Colley in 1922.

The first case of intestinal obstruction was recorded by Bartholin in 1654.

The first record to induce intravenous anesthesia was attempted by Ore in 1872. He used a solution of Chloral hydrate.

As far back as 1667 Hooke experimentally proved that the essential feature of respiration was the blood changes in the lungs.

The deformity now known as Dupuytren's contraction was described by Plater in 1610. Henry Clive, in 1808, included this abnormality among his surgical lectures. Dupuytren's classical description appeared in 1831.

The first case of torsion of the omentum was presented by Marchette in 1852. Twenty-nine years later Oberst gave a detailed description of this condition.

Modern literature attributes to recent investigators the recognition of regeneration of the liver after partial resection. Podwyssozki, in 1886, and Ponfick, in 1896, observed regenerative changes in the liver of rats, cats, guinea pigs, and rabbits. Both noted taat loss of liver substances was repaired by proliferation of liver cells.

VITAMIN REQUIREMENTS OF MAN

IV. VITAMIN B_1

● The multiple nature of vitamin B has been definitely established by intensive research within the past decade. Considerable quantitative information is now available concerning the requirements of certain species of animals for the various factors contained in the vitamin B complex. At the present time, however, the anti-neuritic vitamin B_1 is the only one of these factors for which the minimum requirement for man can be postulated.

Beriberi-preventing diets of Chinese coolies and natives of Java have been estimated to contain 200 International units of vitamin B_1 (1). Practical use is made of knowledge such as this in the Philippines, where the Bureau of Science, in a successful effort to combat beriberi, dispenses tikitiki (vitamin B_1 concentrate from rice polishings) containing approximately 200 International units of vitamin B_1 per daily dose.

It is generally agreed that the absolute requirement for this factor may be variable, depending upon such factors as size and caloric intake of the individual. However, equations have been derived which take into consideration some of these variables and are useful in estimating the adult vitamin B_1 requirement (2).

Application of these equations indicate that approximately 225 International units of vitamin B_1 per day are required for the average American adult. The average daily infant requirement has been estimated to be 50 International units, increasing to 200 units at the time of adolescence (1). The League of Nations Technical Commission recommends a daily intake of over 150 International units for pregnant and lactating women (3).

While it may be possible to estimate the daily intake of vitamin B_1 which will prevent clinical beriberi, it is not yet possible to state the minimum amount of the vitamin which, when imposed on an otherwise adequate diet, will promote optimum nutrition. There is increasing belief that some of the vague disorders, noted clinically, may be in reality manifestations of suboptimal vitamin B_1 intake (4).

Today, we have the new concept of nutrition which recommends the intelligent inclusion in the varied dietary regime of foods with known nutritive values—thereby insuring that the individual is not dwelling in "the twilight zone of nutrition". Thus has arisen the concept of "protective foods".

Results of formal bio-assay have established many commercially canned foods as valuable sources of vitamin B_1 (5).

Incorporation in the diet of the wide variety of foods—made available throughout the year by commercial canning—will assist in the acquisition of an adequate supply of vitamin B_1, as well as other members of the B complex, essential to human nutrition and usually occurring in nature along with the antineuritic factor (6).

This is the twenty-fifth in a series of monthly articles, which will summarize, for your convenience, the conclusions about canned foods which authorities in nutritional research have reached. We want to make this series valuable to you, and so we ask your help. Will you tell us on a post card addressed to the American Can Company, New York, N. Y., what phases of canned foods knowledge are of greatest interest to you? Your suggestions will determine the subject matter of future articles.

The Seal of Acceptance denotes that the statements in this advertisement are acceptable to the Council on Foods of the American Medical Association.

For bland diet therapy, especially ULCER cases—PABLUM

FAR too often the bland diet prescribed for gastric ulcer, colitis, and similar gastro-intestinal disorders is a deficient diet. An analysis made by Troutt of ulcer diets used by 6 leading hospitals in different sections of the country showed them to be "well below the Sherman standard of 15 milligrams" in iron and low in the water-soluble vitamins.[1] "Vitamin B would appear to be represented at a maintenance level in most cases," writes Troutt, "but the possible relation of vitamin B to gastro-intestinal function and appetite should make one pause before accepting a low standard."

Although Pablum has a low fiber content it is 37 times richer than *farina in iron and in* calcium, 4 times richer in phosphorus, and 4½ times richer in copper.

Low in Fiber—High in Iron

Pablum is the *only food rich in a wide variety of the accessory food factors that can be fed over long periods of time without danger of gastro-intestinal irritation.* Its fiber content is only 0.9%. Yet Pablum contains 37 times more iron than farina and is an excellent source (+ + +) of vitamins B and G, in which farina is deficient. Supplying 8½ mgms. iron per ounce, Pablum is 8 times richer than spinach in iron.

Rich in Vitamin B

The high vitamin B content of Pablum assumes new importance in light of recent laboratory studies showing that avitaminosis B predisposes to certain gastro-intestinal disorders. Apropos of this, Cowgill says, "Gastric ulcer is another disorder which can conceivably be related to vitamin B deficiency. Insofar as the treatment of this condition usually involves a marked restriction of diet the occurrence of at least a moderate shortage of this vitamin is by no means unlikely."[2]

Requiring no further cooking, Pablum is especially valuable during the healing stage of ulcer when the patient is back at work but still requires frequent meals. Pablum can be prepared quickly and conveniently at the office or shop simply by adding milk or cream and salt and sugar to taste. Pablum has the added advantage that it can be prepared in many *varied ways—in muffins, mush, puddings, junket, etc. Further, Pablum is so thoroughly cooked that its cereal-starch has been shown to be more quickly digested than that of farina, oatmeal, cornmeal, or whole wheat cooked four hours in a* double boiler (studies *in vitro* by Ross and Burrill[3]). In addition to the above advantages, Pablum is the only base-forming cereal (except Mead's Cereal which is the uncooked form of Pablum).

Pablum (Mead's Cereal thoroughly cooked) consists of wheatmeal, oatmeal, cornmeal, wheat embyro, alfalfa, yeast, beef bone, iron salt and sodium chloride. [1-3] Bibliography on request.

The Treatment of Amebic Colitis with Diiodohydroxylquinoline (Diodoquin)*

By

DANIEL N. SILVERMAN, M.D., F.A.C.P.†

NEW ORLEANS, LOUISIANA

DURING the past ten months, from June, 1936, to April, 1937, a certain number of cases of amebic colitis have been chosen for treatment with a new drug, diiodohydroxylquinoline, represented to the trade as Diodoquin. Up to the time of this investigation this preparation had not been used in a sufficient number of cases to establish the correct dosage or to evaluate its general amebicidal value in amebic infection of the bowel. The daily dosage required to control the disease without deleterious effects and the number of days necessary for such dosage had not definitely been determined. Similar drugs to the one being reported upon in this communication have been used with encouraging results. Their similarity to Diodoquin is based upon the iodine constituent of the oxyquinolines, some of which contain sulphur. Diodoquin differs from the others in the amount of iodine in the compound. The former contains not less than 63.9% of iodine while the other preparations on the market contain about 50% less of this element.

This additional proportion of iodine has not given any deleterious reaction, in fact no appreciable toxic symptoms have manifested themselves. These observations were brought out in view of the administration of twice the daily dosage recommended by the manufacturer. The larger quantity was utilized in several instances because of the severity of the infection, the extensive pathology observed in the lower colon, accompanied by intense focal and systemic reactions. In such persons the larger doses were tried in order to increase the concentration of the drug in the intestinal tract and thereby inhibit the action of the amebae.

As stated above, reports on the treatment of amebic colitis with this new preparation, diiodohydroxylquinoline, are very meagre. Only mention has been made by some observers of the employment of this drug for the condition in question. For example, Tenny speaks of the encouraging results obtained in a clinical way and that he is exhibiting it in suspicious cases of a chronic low grade ameboid infection. This writer believes Diodoquin meets the requirements of an amebicide free from toxicity and practical for routine use in the treatment of active cases. Tenny does not give any definite information on the number of cases he treated, the types of cases, the dosage of the drug, or on the very important criterion of permanent results, namely, repeated negative examinations of the stools for the ameba.

In a recent article entitled "The Management of Chronic Relapsing Amebiasis," Hummel (2) gives an analysis of his 123 such cases. In one patient only he treated the amebic infection with the new preparation. He emphasizes the increased amebicidal action of diiodohydroxylquinoline because this preparation has the additional action of an atom of iodine in the molecule. Trophozoites and cysts disappeared from the stool in five days. However, recurrences were frequent, and, Hummel reiterates the prospects of cure are remote with any of our present means of treatment once the case has become chronic.

Craig (3), has treated 8 carriers (chronic amebic colitis) with disappearance of the parasites from the stools. His subjects were free of symptoms when treatment was instituted.

In the present report the author has the opportunity to discuss the analysis of 25 cases of amebic colitis treated with this drug. Among these twenty-five patients were nine acute fulminating cases. Their histories were of sudden onset from a few days to two weeks before consulting a physician. Since there were no other cases of acute amebic dysentery similar to mine in the reports of other writers that had made use of Diodoquin, the author was afforded an initial opportunity of observing the effects of this drug on acute amebic colitis, as evidenced by the changes in the living pathology presented in the rectum and sigmoid through the sigmoidoscope. The dosage of the preparation as herein established is much larger than previously recommended. The daily dosage employed in this series of patients has proven non-toxic and of maximum therapeutic value. The quantity heretofore recommended has been from 7.5 to 15 grains every 24 hours, but the author has established a daily dosage of 22.5 to 30 grains without observing any toxic effects or untoward results.

In the 16 chronic cases, there were only two with diarrheal symptoms. The other 14 had varied complaints, particularly abdominal distress comprising upper and lower abdominal pain, indigestion, headaches, malaise and weakness. In this connection we must not overlook the always present possibility that amebic colitis exists in every case of undiagnosed abdominal condition.

As an example of acute fulminating dysentery caused by Endamoeba histolytica and showing the satisfactory results of treatment with sufficient dosage of Diodoquin, the following case is described:

M. H., white male, age 50, was admitted to the hospital on February 2, 1937, complaining of severe griping sensations in the abdomen, malaise and frequent bloody mucus stools of one week's duration. On palpation of the rectum, a hard, irregular mass, suggesting possible carcinoma was detected. The proctoscopic examination showed this mass to be ulcerated and necrotic with numerous ulcers in the rectum and sigmoid. Trophozoites of Endamoeba histolytica were found in large numbers. On February 6, treatment was started with 10 grains of Diodoquin three times daily. February 10th, palpation of the rectum failed to reveal any evidence of the previous tumor formation. Inspection showed some granulation of the mucous membrane with puckering of a few ulcers. February 13th, ulcers were still visible and the stools contained cysts of

*The material used in this investigation was furnished by G. D. Searle & Co.

†Professor of Gastro-enterology, Tulane University of Louisiana, Graduate School of Medicine.

Submitted April 7, 1937.

the ameba. February 15th, after 9 days of treatment, with a total dosage of 270 grains of Diodoquin, the patient was symptom free. Treatment was continued and on February 19th the rectum still showed one large ulcer with granulation tissue in its area. February 21st no amebae were found in the stool. February 25th, 19 days after instituting treatment, all evidence of rectal and sigmoid pathology had disappeared and the drug was discontinued. Up to the present writing, April 5th, the stools, obtained at weekly intervals, after saline purges, have not shown any amebae.

An example of *severe amebic dysentery* in which treatment with Diodoquin was begun two weeks after the onset of intense diarrhea with muco-sanguinous stools, was Dr. R. Q., who showed extensive ulceration of the rectum and sigmoid with numerous trophozoites of the ameba on January 2, 1937. He was given 7.5 grains of Diodoquin three times daily and on January 11 no ulcers were seen in the rectum or sigmoid on proctoscopy. Upon January 12th, cysts were found in the stool but on January 14th no trophozoites or cysts were recoverable. Treatment was discontinued on January 16th. Repeated examinations of the saline-purged stools fail to reveal any Endamoeba histolytica at the present writing, April 5, 1937.

The chronic cases of amebic colitis, 16 in number, were administered 9 tablets of Diodoquin per day, for an average of 16 days. Fifteen of these patients have been free of symptoms for periods ranging from one month to eight months. They have shown no recurrence of amebae in the stools. One patient continues to have diarrhea of a watery nature because of an associated flagellosis although no amebae have recurred.

SUMMARY

In a preliminary study of 25 cases of acute and chronic amebic colitis treated with a newer oxyquinoline compound of iodine containing approximately 64% of iodine, beneficial results were obtained in a comparatively short period of drug administration. These results have been observed over varying lengths of time, from one to nine months. The benefits were measured by the effects, in acute cases, on the pathology in the rectum and sigmoid as determined by repeated sigmoidoscopic examination before, during and following treatment. Results were determined in both acute and chronic cases of amebic colitis by microscopic study of saline-purged stools at regular intervals of one week. Invariably the amebae disappeared from the stool following sixteen days of treatment. The writer finds that the dosage of diiodohydroxylquinoline should be 22.5 grains to 30 grains per day. The drug is practically non-toxic, with headache being one predominant symptom in the three patients that complained.

A Complement Fixation Test for Amebiasis with an Increased Antibody Content*

By

EMIL WEISS, M.D.

and

LLOYD ARNOLD, M.D.

CHICAGO, ILLINOIS

DURING the last few years it was observed that infections with ameba histolytica are of more frequent occurrence than was previously anticipated. The difficulties of diagnosing this infection at an early stage are manifold. A number of intestinal disorders resemble amebiasis very closely and frequently the final diagnosis rests entirely with the laboratory tests. The conditions for examination of fresh and stained fecal smears are not always satisfactory although the clinical findings indicate amebiasis. Similar experiences are encountered with amebic cultures. In addition the number of reliable laboratory workers, capable of diagnosing amebae in fresh smears or preparing satisfactory cultures is relatively small. In the early stage of its development, the complement fixation test for amebiasis was considered only as a secondary test to confirm other laboratory tests or clinical findings (7, 8, 10, 11, 15). The lack of appreciation of the complement fixation test for diagnostic purposes was due to its relatively low percentage of positiveness in established amebic infections. The low percentage of positiveness was caused mainly by the weak antigen and the relatively small amount of antibodies used in the test. Several attempts were made to improve the antigen (6, 9, 12, 17, 18, 21), but no one seems to have tried to utilize the antibodies in a more satisfactory manner. Weiss and Arnold (21, 22), introduced several innovations in the ameba complement fixation test. They prepared a stronger antigen, and simplified the antigen titration. The improved antigen could be used in much smaller amounts, thus avoiding hemolysis caused by the presence of a relatively large amount of alcohol in the extract. They also showed that if large amounts of serum (1 c.c. instead of 0.1 c.c.) were used in the test, the additional antibodies were fixed, in fact the stability of the procedure increases proportionately. In addition they used as a positive control a rabbit serum prepared with ameba cultures or alcoholic extracts from amebae. The use of the rabbit immune serum instead of a positive serum offers the advantage, that it is surely positive and aways available as a control. These improvements resulted in a higher percentage of positiveness, without

*Department of Bacteriology of the University of Illinois, College of Medicine, and the Illinois State Department of Public Health.
Submitted April 8, 1937.

increasing the number of nonspecific positive reactions.

The great interest evoked by this test and the possibility of increasing the sensitiveness of this procedure led to additional studies. As the outcome of these experiments an improved procedure was developed which is described below.

TABLE I

The influence of natural amboceptor on the complement fixation test for amebiasis

Number and kind of sera	Reaction	½ Units of Immune Serum Amboceptor Without	With
42	Hemolysis	—	41
Normal	Slight hemolysis	—	1
	No hemolysis	42	—
56	Hemolysis	—	49
Syphilitic	Slight hemolysis	—	1
	No hemolysis	54	1
72	Hemolysis	—	4
Amebic	Slight hemolysis	—	10
	No hemolysis	72	58

EXPERIMENTS

I. *The content in natural amboceptor of normal, syphilitic and amebic sera.*

The employment of larger amounts of serum in the complement fixation test necessitates a closer study of the natural amboceptor in various sera. It has been known for a considerable length of time, that every human serum contains a natural amboceptor for sheep cells in some quantity and that the amount varies in every serum. By using larger amounts of serum in the fixation test, the amount of natural amboceptor increases correspondingly. It appeared therefore, worth-while to investigate the amount of amboceptor in various sera and to determine to what extent this natural amboceptor may interfere with the outcome of results in the complement fixation test.

Forty-two normal, fifty-one syphilitic and seventy-two amebic sera were inactivated for one hour at 55-56° C. and then complement fixation tests for amebiasis were performed, in one series without amboceptor and in the other series with five units of amboceptor. The results are given in Table I. It is evident, that natural amboceptor has little influence on the outcome of the fixation if the immune serum-amboceptor and the blood cells in the hemolytic system are used in sufficient quantities.

II. *Comparative studies of the complement fixation test for amebiasis with increasing amounts of serum.*

One hundred and eighty-one sera of various stages of amebiasis, three hundred and ten syphilitic sera and four hundred and twenty-four sera of various other diseases were included in this study. Only sera of patients were studied in which the diagnosis had been well established by other laboratory methods and clinical findings. The detailed results are given in Table II. The advantage of using larger amounts of serum is plainly noticeable in every stage of amebiasis. The increase of non-specific positive reactions is rather small and amounts to less than one per cent.

THE TEST

Apparatus and glassware: Pipettes, tubes and other glassware are the same as is used in any other complement fixation test. Both incubator and water bath easily adjustable to 37° C., and varying not more than between 36°-38° C. are satisfactory. In the proposed procedure the reagents are used in a higher concentration than in most complement fixation tests. It is therefore essential that the tubes be vigorously shaken to insure a uniform mixture of added reagents. For this reason the use of shaking machine preceding both incubations appears advisable.

Antigen preparation: The liquid contents of a forty-eight to seventy-two hour culture of endameba histolytica grown on any of the satisfactory media (2, 3, 4, 5, 13, 14, 19) are poured in centrifuge tubes and centrifuged for fifteen minutes at high speed. The supernatant fluid is then removed and the sediment is transferred to wide glass

dishes, covered with a small amount of acetone and allowed to dry at 37° C. The dry residue is scraped off with a sharp knife and the powder extracted with absolute alcohol in the ratio of 1:20 for two weeks at 55° C. in a water bath. The extract gradually assumes, a distinct yellow color. The fluid is then removed by filtration through paper or by centrifuging from the sediment. The extract is then ready for antigen titration. If the subsequent titration shows a weak extract, this can be corrected by concentration of the antigen through evaporation at 37° C. to the desired strength. If the antigen is too strong, it can be satisfactorily adjusted by diluting it with a sufficient quantity of absolute alcohol. The completed antigen should be kept at room temperature in a tightly stoppered bottle in order to avoid evaporation of the alcohol. Rubber stoppers are preferred to ordinary corks.

Titration of the antigen: Twenty Wassermann tubes are placed in two rows of a rack. Increasing amounts of the extract, 0.05, 0.1, 0.2, 0.3 c.c. diluted 1:10; 0.2, 0.25, 0.3 c.c. diluted 1:5; 0.2, 0.25, 0.3 diluted 1:2.5 are placed in the ten tubes of the front row, and the same amounts in the corresponding ten tubes of the back row. Each tube of the front row receives 0.1 c.c. of an inactivated negative serum and each tube of the back row receives 0.1 c.c. of a strong positive (amebic) serum. Normal saline is added to each tube to make up 2.3 c.c. Each tube of both rows receives 0.05 c.c. of undiluted complement. The tubes are shaken vigorously and placed in a water bath for one hour at 37° C. After the incubation five units of amboceptor in 0.1 c.c. saline and 0.05 c.c. of a 50 per cent suspension of washed sheep blood cells are added to each tube. The tubes are again shaken vigorously and placed in a water bath for one hour at 37° C. The results are then read. The largest and smallest amount of antigen giving complete inhibition with a positive amebic serum and hemolysis with a normal serum is determined. The amount of antigen midway between the largest and smallest specific dose is then selected as the antigenic dose. (See Table III).

The patient's serum: The sera are inactivated for one-half hour at 55-56° C. Fresh sera are inactivated after separation from the blood clot, and then preserved in the ice-box until used. A mixture of several normal sera are used as a negative control. In the absence of strong positive sera, immune serum of rabbits is used. The immune serum is prepared by intravenously inoculating rabbits twice weekly with saline washings of ameba cultures in increasing amounts. Six to eight inoculations usually suffice and the rabbits are bled two weeks after the last inoculation. The smallest dilutions of the immune serum still giving strong positive reactions are used in the ab-

*Additional dilutions of amboceptor can be prepared, if necessary.

sence of strong positive human sera. Old, contaminated or hemolytic sera should not be used.

The complement: A mixture of sera of several guinea pigs is used instead of the serum of a single guinea pig. Otherwise the same rules apply as generally practiced in the Wassermann test. Five hundredths of a c.c. of undiluted complement is used instead of an 0.5 c.c. of a 10 per cent dilution in order to allow a greater relative volume for the serum.

Red Blood Cells: Sheep cells were selected in preference to human blood cells, the former being more available in most of the laboratories where Wassermann tests are performed. The washing and dilution of the blood cells for the test is carried out in the same way as in any other complement fixation test. Five hundredths of a c.c. of a 50 per cent suspension of red blood cells is used instead of 0.5 c.c. of a 5 per cent suspension in order to allow more volume for the serum.

Sheep blood hemolysin (amboceptor): Amboceptor is prepared in the same manner as that used in the Wassermann test. The amboceptor is titrated against fixed amounts of complement. Increasing dilutions of the amboceptor are prepared and 0.1 c.c. of each dilution is placed in a series of ten tubes. To each tube 2.3 c.c. saline and 0.05 c.c. of undiluted complement are added. The tubes are shaken and placed in a water-bath for one hour at 37° C. After the incubation 0.05 c.c. of a 50 per cent suspension of sheep cells are added to each tube. The tubes then are shaken and placed for one hour in the water bath at 37° C. The highest dilution of the amboceptor causing complete hemolysis is called one unit. Five units of the amboceptor are used for the antigen titration and the main test. The biphasic incubation in the amboceptor titration is intended to expose the complement to the incubator temperature for the same length of time as in the antigen titration and the main test. The amboceptor should be titrated each time the complement fixation test is performed. (See Tables IV and V).

The Main Test: Racks with two rows of tubes are used. The tubes of the first row receive the titrated amount of antigen, while the tubes of the second row receive saline instead of antigen and serve as serum controls. Each tube of the first and second row receives 2 c.c. of the respective serum. The last tube in the first row receives, instead of 2 c.c. serum, an equivalent amount of saline; this tube serves as antigen control. All tubes then receive saline to make up 2.3 c.c. and then 0.05 c.c. of undiluted complement is added to each tube. The tubes are then vigorously shaken and placed in the water-bath for one hour at 37° C. After the incubation five units of amboceptor in 0.1 c.c. saline and 0.05 c.c. of a 50 per cent suspension of sheep red blood cells are added to each tube. The tubes are again vigorously shaken and placed in the water bath for one hour at 37° C. The results are then recorded. (See Table VI).

Controls: (1) *Serum controls.* Each serum including the positive and negative control should have a serum control. All serum controls should give hemolysis. (2) *Antigen control.* This control should show hemolysis; inhibition of hemolysis would indicate too large an amount of antigen used in the test. (3) *Positive control.* This should always show complete inhibition of hemolysis. (4) *Negative control.* This should show hemolysis. (See Table VI).

Reading of Results: After the second incubation, the controls are examined before the unknowns. In the latter, the tubes showing the same turbidity as before the second incubation are interpreted as strongly positive (++++), tubes showing slightly less turbidity are read as positive (+++) and tubes showing only slight turbidity are called weakly positive (++ or +) respectively. Tubes perfectly transparent are interpreted as negative. The test is repeated with sera showing doubtful reactions.

DISCUSSION

The above described modified procedure for the diagnosis of amebiasis by means of complement fixation represents a definite improvement upon the original method. These improvements embrace a number of details. It simplifies the preparation of the antigen. It was found that repeated washings of ameba cultures do not remove a sufficient amount of bacteria to justify the effort. In addition a large number of amebae are lost as a result of these washings. On the other hand smears from washed ameba cultures still reveal a very large number of bacteria. Bacteria from ameba cultures were transferred to a series of agar plates, the growth was washed off with acetone, dried and the extract prepared in the same way as that from ameba cultures. Such extracts do not give a positive complement fixation with amebic sera. Based on these observations the washings of amebic cultures were eliminated in the modified procedure. A protracted extraction for two weeks at 55° C. results in stronger antigens than if the extraction is limited to two days as previously recommended.

Experiments with increasing amounts of serum have shown that the use of two c.c. of patient's serum instead of 0.1 c.c. or 1.0 c.c. offers definite advantages by using more antibodies and rendering the complement fixation test more stable and consequently increasing

the percentage of positive reactions. This modification of the usual complement fixation test requires detailed consideration.

In the early stage of development of the complement fixation test for syphilis several authors: Bauer (1), Stern (20), Hecht (16) and others, tried to utilize the natural amboceptor of the human serum against blood cells. These attempts failed and in general the reasons were as follows: (1) The amount of natural amboceptor varies in different serums. (2) The procedure of adjusting the amboceptor in every serum separately requires too much time. (3) It was impractical to run many tests simultaneously with such methods, and, finally (4) Frequent absence of any amboceptor or presence of it in negligible amounts in some human serums. The possible interference of the natural amboceptor on the outcome of the complement fixation test in our procedure has been avoided by using in the antigen titration and main test five units of immune serum-amboceptor thus rendering the eventual influence of natural amboceptor negligible. In addition

The beneficial improvements especially concern the early diagnosis of amebiasis, the slower gradual disappearance of positive reactions following treatment, the diagnosis in untreated and neglected chronic cases, and the differential diagnosis of other chronic disorders. An elaborate presentation of statistical findings of the improved procedure in relation to the original method and other tests is reserved for a special paper.

Amebiasis has received some attention from the public health standpoint. It was found necessary a few years ago in Illinois to develop a practical method of determining the reservoirs of infection for endameba histolytica. The examination of the feces was slow, time consuming and expensive. There were not enough trained parasitologists to do the work. It became apparent to all public health administrators that some practical method would have to be devised to determine the extent of the infection and reserve the more exact microscopic fecal examination methods for studying and substantiating some other procedure

TABLE VI

The main test

Tubes	Antigen	Normal Saline (0.85%)	Inactivated serum (½ hr. at 55° C.)	Undiluted Complement	First Incubation	5 Units Amboceptor	50% sheep red blood cells	Second Incubation
1	Titrated amount	q.s. 0.3 c.c.	Unknown 2 c.c.	"	The tubes are shaken vigorously and placed in a water bath for one hour at 37° C., then are added:	0.1 c.c.	0.05 c.c.	The tubes are shaken vigorously and placed in a water bath for one hour at 37° C., then the results are read.
2	0	"	"	"		"	"	
3	Titrated amount	"	Normal 2 c.c.	"		"	"	
4	0	"	"	"		"	"	
5	Titrated amount	"	Amebic 2 c.c.	"		"	"	
6	0	"	"	"		"	"	
7	Titrated amount	q.s. 2.3 c.c.	"	0.05 c.c.		"	"	

it has been shown that the additional amount of amboceptor caused by the presence of natural amboceptor could not affect the results, even if large amounts (2.0 c.c.) of serum are used. Therefore, a special control for natural amboceptor containing 2.0 c.c. patient's serum, saline quantity sufficient to make 2.4 c.c., 0.05 c.c. undiluted complement and 0.05 c.c. 50 per cent red blood cells suspension can be safely omitted. For the same reason it appears unnecessary to remove the natural amboceptor from the patient's serum by treating it preceding the test with washed blood cells. The changes in preparation of amboceptor dilutions and titration of amboceptor were made in order to allow more volume for the patient's sera. Smaller amounts of amboceptor are used in corresponding higher concentrations, otherwise the same amounts are tested in the same way as in the original procedure. As a result of these changes in the technique, the amount of antibodies used in this test is increased 100 per cent without changing the total volume. Proportionately the increased amount of patient's serum increases the stability of the test requiring considerably larger amounts of complement to render a positive reaction negative. The percentage of non-specific positive reactions has not been increased by these modifications.

which could be used as a practical public health laboratory procedure. We felt the need of a rapid cheap method to allow us to evaluate the relative health hazards in a community.

The relatively few cases we have been able to study lead us to believe this complement fixation method can be used for this purpose. The four plus and three plus reactions can be considered as positive. There were 87 per cent of the carriers, 90 per cent of the chronic and 80 per cent of the acute cases of amebiasis positive when we used 2 c.c. of the serum. All of these had positive stool findings.

SUMMARY

An improved procedure for diagnosis of amebiasis by means of complement fixation has been described with the following advantages:

1. Simpler preparation of a stronger antigen.
2. Increased positiveness in early and treated cases.
3. Increased stability of the test by the use of larger amounts of patient's serum.
4. A more satisfactory correspondence between this test, other ameba tests and clinical findings.

The Digestive Qualifications of Man

By

E. G. WAKEFIELD, M.D.*

and

CHARLES W. MAYO, M.D.†

ROCHESTER, MINNESOTA

PATIENTS frequently ask physicians questions concerning the foods they should or should not eat. These questions almost invariably show that such patients have dietary prejudices. Inquiry reveals that these prejudices have arisen from one of the following causes: (1) a misinterpretation by the patient of legitimate dietary information received from physicians and dietitians; (2) an erroneous conception obtained from those whom we shall call, not for the lack of a better descriptive word, but for the sake of propriety, charlatans; and (3) erroneous information concerning the functions of the colon, the structure of the colon, and the biologic proclivities of man. Those who have dietary prejudices often believe that man suffers from digestive disorders which result from displacement of various segments of the digestive tube as a result of the evolutional influences which have caused him to assume the upright position. This information is received from various sources, frequently from the lay press. A misinterpretation of legitimate dietary information is a negligible source of confusion. A study of some of the dietary prescriptions in the possession of certain individuals reveals a most extraordinary array of ingenious combinations of foods in order to procure certain supposed physiologic effects.

A disquisition on dietary prejudices reveals that patients have spent sufficient time and energy to have become correctly informed. This situation is not the fault of physicians who are interested in diet and metabolism or the fault of well-trained dietitians. Somewhere between the dietetic experts and the general practitioner of medicine is a gap which has been generally considered nobody's field. From time to time, without any very serious thoughts on the subject, startling statements are made about what the "natural foods" for man are. Such statements bring forth arguments, often fallacious, which would indicate that man in his primitive state was either a herbivore or a carnivore.

It is the object of this communication to review what is known about the natural foods of man and to compare briefly the structure and function of the alimentary canal of man with that of the Herbivora and the Carnivora, with special reference to the so-called disadvantages which have been thrust on man's digestive equipment by his upright position.

There is not a more appropriate place to begin this consideration than by observing that the number and variety of vegetable and animal products included in the daily diet of the average healthy person are extensive. To this list of materials are added further complexities by changes which take place between the time they are collected and the time they are consumed. These changes are brought about by freezing, cooking, drying, and various degrees of decomposition; some of the changes are beneficial and some are not. In spite of partaking of this ever increasing number of foods, and notwithstanding the increasing perplexities of modern culinary art, which imparts a more luscious flavor to foods, the human race as a whole enjoys digestive health.

It is obvious that the versatility of the human digestive system, which is evidenced by the number and variety of foods ingested daily, has not been gained in recent times. This versatility, so far as the human species is concerned, is an ancient endowment. It was first manifested at a period in the past when through continental elevations and subsequent aridity of the climate the dense forests of Asia began to be thinned out and to recede toward the equator. In time these changes of the forests became great enough to bring about a shortage of food for the arboreal inhabitants, among which was man. Inasmuch as man at that time had the digestive system that we know him to possess at the present time, he was able to adapt himself to a terrestrial habitation and partake of practically any food offered by the mass of the forests and plains, and was able to eat the flesh of fish, fowl, and other animals. Through inability to obtain constant supplies of food, primitive man on occasion partook of a great variety of food in order to sustain life. To illustrate that primitive man often consumed any available food that he could lay his hands on, we may cite the fact that Mr. Cottam, of the U. S. Department of Agriculture, has recently examined for us the feces obtained from a mummy of a primitive race that inhabited the rocky shelters of the Ozark Mountains many centuries ago (1). The feces of this mummy

*Division of Medicine, The Mayo Clinic.

Submitted February 26, 1937.

contained particles of black oak acorns, fruit of the sumac, charcoal, and insects. If we could obtain comparable data on the foods of primitive peoples at the various ages of man's existence, we would have in all probability a vast amount of data to illustrate the extent of different foods that man has eaten in order to maintain health and life.

The earliest historical records of what man ate, which are comparatively recent as compared to the length of time man has existed as he now is, have been obtained from the translations of the papyri of ancient Egypt. These translations indicate that man ate animal and vegetable products and oils; the fresh leaves of the garden cress and the common mustard were eaten as salads. Grapes, figs and pomegranate were served as fruits. The ancient Egyptians did not eat much meat. They did not abstain from eating meat because they did not like it, but because they did not have it. The cow was sacred; however, it was all right to kill and eat an ox. In most districts the meat of goats, sheep and hippopotami was eaten when available. Herodotus recorded that the foods given the laborers during the building of the Pyramids consisted in large part of radishes, onions and garlic. According to translations of Homer's Odyssey, the ancient Greeks enjoyed a much greater variety of both meats and vegetables than did the ancient Egyptians. The former ate flesh of animals that we eat and enjoy, and in addition, they partook of Carnivora such as the dog and fox.

Whether the digestive system of man possesses the anatomic and physiologic qualification to digest the number and variety of foods that he eats and still enjoys digestive health, requires consideration of the chief sources and properties of the foods eaten and the digestive means of reducing these foods to end products which can be absorbed and utilized for energy by the tissues. There has been considerable experimental work done on the digestion and utilization of various foods by man, but this work alone is not enough. These experiments have been confined to the digestion of specially prepared foods consisting mainly of fats, proteins or carbohydrates. Such work seldom takes into consideration the mechanical handling of the undigestible residue of natural foods. This mechanical manipulation during digestion of natural foods is carried on by specially designed structural arrangements of the alimentary canal. The comparative anatomist is so familiar with special digestive structures which are required for the digestion of different natural foods that he can predict the types of natural foods eaten by a species.

Plants and animals are the chief sources of foods for mammals. The foods of animal origin may be divided into flesh and insects. If under natural conditions an animal partakes solely of flesh, it is designated as a carnivore; if it partakes only of plants, it is called a herbivore; and if it partakes only of insects, it is known as an insectivore. An animal that can eat either flesh or vegetable foods is known as an omnivore. This classification is helpful because it grossly predicates special anatomic structural arrangements of the alimentary tube of each group.

Before considering the differences in the structural arrangements of the digestive tubes of each group, it is well to review some of the properties of foods. All foods are chemically inactive, are insoluble under ordinary conditions, and usually are colloids. On the natural death of any food substance the chief activity is a tendency to decay. However, after ingestion of food by mammals it is subjected to the action of an organic system of catalysts known as enzymes. The

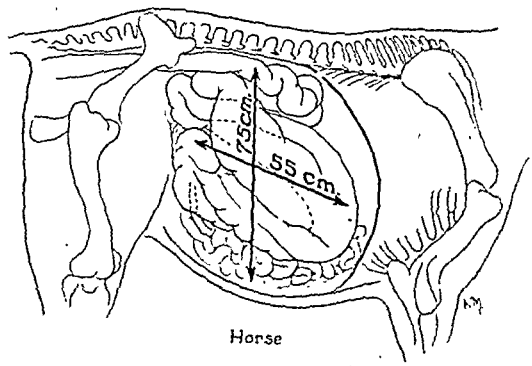

Fig. 1. Horizontal and vertical measurements of the abdominal cavity of a well developed horse.

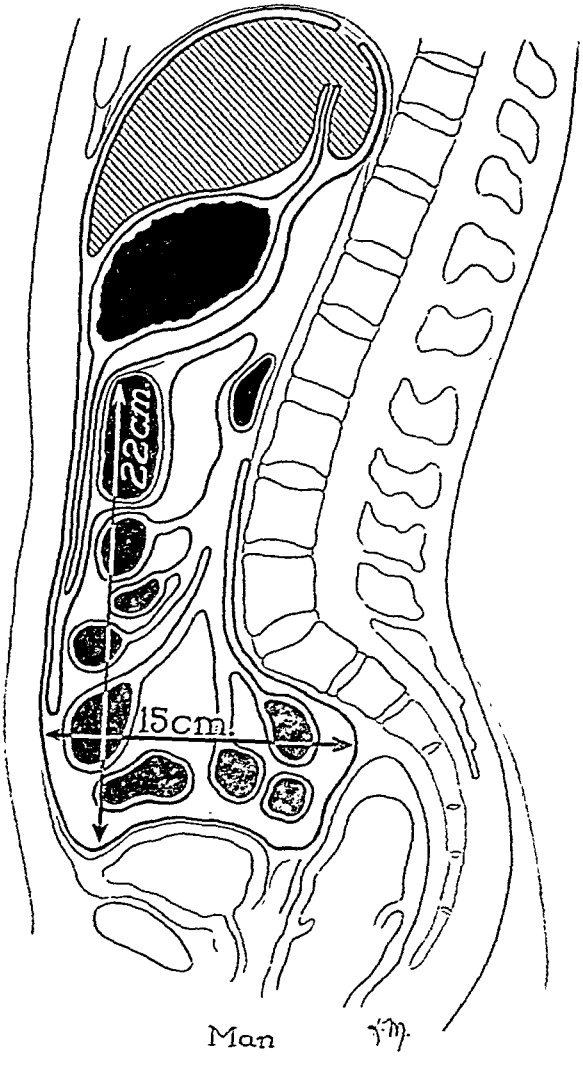
function of enzymes is to reduce the food to simple compounds which can be absorbed. One great difference in the variety of enzymes in the secretion of various mammals is that the salivary secretion of the Carnivora, such as dogs, does not contain a starch splitting enzyme.

The great difference in the composition and digestibility of the natural foods is their varying content of cellulose and such substances as chetin, but here we are mainly interested in cellulose. Cellulose cannot be digested by the enzymes which are secreted by the digestive glands of mammals. The digestion of cellulose requires specialized structures which will retain the food long enough in the gastro-intestinal tract to make possible its digestion. Such specialized digestive apparatuses are observed in such species as the ox and the horse. Because foods which contain cellulose are less likely to undergo putrefaction than are foods which do not contain cellulose, they are susceptible to a longer retention in the body by saccular and convoluted extensions of the colon, stomach, or both. This longer retention is necessary in order that the enzyme citase, which is contained in the foods that contain cellulose, may hydrolize them to starches so that the endogenous enzymes may then proceed with the usual digestion of starch. Because of the low nutritional value of foods that contain cellulose, animals that partake of such foods under normal conditions are forced to eat constantly, and therefore there are two reasons for a great alimentary capacity.

The Carnivora may be cited as a group of mammals that do not have either a complex stomach or colon. All sections of the alimentary tube of Carnivora are supplied with thick muscles to rush the food along. That the Carnivora can maintain a healthy existence on mixed foods like those taken by man is common knowledge obtained from daily observations on the domesticated dog. In many ways the structure of the alimentary tube of the Carnivora is similar to that of man. The colon of man has rudimentary sacculations and is comparatively longer and larger in diameter than that of the Carnivora. The first half of the colon of man is somewhat similar to that of the cellulose-digesting mammals.

A survey of the structural arrangement of the alimentary tube of mammals in relation to the digestion of natural foods reveals that its length gives a great deal of information. The alimentary tube of the cat (carnivore) is three or four times, that of man (omnivore) is five to seven times, that of the ox (herbivore) is fifteen times, that of the horse is twenty times, and that of the sheep is twenty-seven times the length of the body respectively. (These measurements must not be considered absolute.) Such measurements seem to emphasize the foregoing structural considerations; they illustrate that man belongs to neither the purely Carnivora nor to the Herbivora; they bear out the fact that man possesses the simplicity of design which characterizes the alimentary tube of the Carnivora and that he possesses some of the added storage capacity of the Herbivora. These comparative differences in structure and length of alimentary tract are helpful in predicting what an animal eats under natural conditions. They indicate that if voluminous foods are to be digested, then capacity is required. They also indicate that man can partake liberally of all types of foods that do not contain large amounts of indigestible bulky matter. They further prove that man can partake of a greater variety of foods than can a carnivore, but that he falls short of the alimentary capacity of the Herbivora. Man therefore can be either a facultative carnivore or herbivore; he possesses a large part of the alimentary structural advantages of both groups.



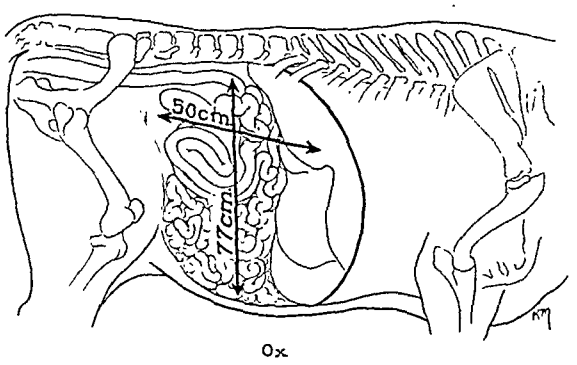


Fig. 2. Horizontal and vertical measurements of the abdominal cavity of a well developed man.

A more intimate knowledge of the structure and function of the digestive apparatus of man may be obtained by briefly reviewing the embryonic development. In a 5 mm. embryo, the digestive system is represented by a straight dorsal tube. This tube has developed embryologically from two segments, the foregut and the hindgut; each segment is found to develop further into the future anatomic structures which will carry on the three important phases of digestion. The anterior section or foregut, combined with the structures of the mouth and throat, will form the alimentary tube and digestive glands down to the distal portion of the duodenum. The distal segment of the foregut and the proximal section of the hindgut form the intestines, and the distal, or the rest of the hindgut portion of the primitive tube, when combined with the structures of the anus and rectum, forms the remainder of the alimentary canal. The function of the first portion of the digestive tube is concerned mainly with selecting, obtaining, masticating, mixing and moving the food along, and also is concerned with the beginning of chemical digestion and absorption. These very important physiologic functions, especially that of selection, cannot be overemphasized. The sight, taste and smell of food are of paramount importance and are fundamental endowments of a species. These senses initiate motor mechanisms which prepare and start the food on its way down the esophagus. These motor functions are under voluntary control. In man and the Carnivora, a protective involuntary reverse motor mechanism, vomiting, which expels disagreeable gastric contents, is operative soon after birth. Sight, taste, smell and the forcing of the food into the esophagus by the voluntary act of swallowing, produce the involuntary motor mechanism of peristaltic action and the secretion of digestive juices. Once the food is in the stomach, the additional factor of gravity is operative. These involuntary forces end with the voluntary discharge of the alimentary dejecta, which is controlled by the anal sphincter. All the accessory digestive glands that pour their secretions through ducts into the digestive tube are developed at appropriate levels. These glands and their secretions usually are similar in structure and function in all mammals. Their differences depend on the concentrations of their secretions and quantity of secretion required at a given time. The function of the enzymes is the same; they are catalytic agents which fit into the complex molecules of the food like a key into a lock. This linkage permits chemical reactions to take place with the formation of compounds which can be absorbed. It is only necessary to state that there is no part of digestion which has received more attention than the function of enzymes. However, digestive disorders that are the result of a deficient supply of enzymes or an overproduction of these organic catalysts are indeed few in number.

Primitive man learned that he might tamper with his daily intake of food and include fasts in his religious ceremonies. However, the regular intake of water was never interfered with; no matter how religious he might feel, man usually allowed himself

Ox

Fig. 3. Horizontal and vertical measurements of the abdominal cavity of a well developed ox.

water to drink. His places of abode were always near a constant supply of water; if he lived in a cave, a stream was nearby. Since the emergence of our piscine ancestry from the sea, the greatest battles for survival have occurred in the vicinity of watering places. Some orders of mammals, the Ruminántia, have special structural arrangements in their stomachs for the storage of water. A more helpful appreciation of the services rendered by water in the processes of digestion and assimilation may be gained by contemplating the actual rate of turnover of this remarkable solvent and carrier by the various digestive organs of man. The salivary glands, stomach, intestinal walls, pancreas, and the lymph return to the blood the water that they drain from it. The minimal volume of water returned in this way is 4000 c.c. A more liberal estimate for this returned volume of water would be 10,000 c.c. At every point in the gastro-intestinal tube attempts are made to conserve and to return to the body certain quantities of water. Some water is lost in the feces, but under normal conditions it is the function of the colon to keep this loss of fluid at a minimum. Under most circumstances the sensation of thirst is adequate to maintain a sufficient quantity of water for digestive processes. However, recently acquired sedentary habits have dulled our sensations, and sufficient amounts of water may not be taken. Of the various types of starvation, the complete deprivation of water leads most rapidly to a fatal termination. A lack of sufficient water may lead to digestive disorders which will be relieved by an adequate intake of water.

When water is ingested, it leaves the stomach rapidly. With the sweeping out of the acid secretions of the stomach, the intestinal fluids become more acid. The osmotic pressure of the intestinal fluids is decreased until an equilibrium is reached. The aqueous portion of the chyme throughout the midgut thus remains in constant electrolytic equilibrium with the extracellular fluids of the body. It is this constancy of electrolytic equilibrium and temperature that makes possible the constant efficiency of the action of the enzymes.

As has been stated, the colon of man in its proximal half is thin-walled, somewhat larger in diameter, and longer than that of a carnivore of comparable size, and in addition the human colon has rudimentary sacculations. These sacculations might create superficial speculation that the colon of man possesses digestive functions, and that man is therefore closely related to the Herbivora. Welch (2) recently has determined that the digestion of organic materials, such as proteins, carbohydrates and fats, is completed in the small intestine of man.

Because of the upright position of man, the alimentary substances are moved against the force of gravity in passing from the pelvic coils of the small intestine to the hepatic flexure and again in passing the proximal part of the left half of the colon to the splenic flexure. These obvious facts have caused considerable speculation by pessimists who believe man is biologically inferior. We have made investigations to determine if a comparable situation existed in some of the domesticated four-footed animals. In order to make these comparisons, dissections and measurements were performed on the horse, the cow, the pig and the cat. During these dissections the idea occurred to us that the possible distances that the alimentary substances might be raised against gravity in any species was limited by the following conditions: (1) the vertical diameter of the abdominal cavity and the variations of the distances which are brought about by changes in position; (2) the length of the mesentery which controls the distance that any segment of gut may move within the abdominal cavity during changes in position; (3) the degree of the fixation of the intestines, especially the colon, at flexures; and (4) the tonicity and elasticity of the abdominal wall.

The vertical diameter of the abdominal cavity represents the maximal distance that the alimentary substances may be moved against gravity. However, no species keeps the abdomen in the same position all the time. In this study it was impossible to compare more than the upright or standing position. By dissection and measurements it was found that when the animals studied were in the upright position the length of the mesentery permits the small intestine to reach and normally occupy the most dependent portion of the abdominal cavity, and that some part of the colon is always attached to the uppermost part of the abdominal cavity. The length of a line which connects the dependent portion of the abdominal cavity with the upper part is therefore the distance the alimentary substance must be raised against gravity in every case. Thus, our problem in comparing the distances the alimentary substance is raised against gravity in all the species was simple and could be determined with a fair degree of accuracy. The measurements shown in Figures 1, 2 and 3 illustrate the distance the alimentary substance is raised against gravity. For man, this distance is proportionally no greater than for the animals studied. The greater fixation of the colon of man is probably advantageous. If there should be only slight fixation of the human colon there still would not be proportionally any more work done by the intestines of man than is done by the intestines of the horse and cow.

SUMMARY

It is a fundamental endowment of the human species to eat a larger number and variety of foods than does

any other mammal. Any food is "normal" for man so long as it does not contain large amounts of cellulose, chetin or similar materials which require specialized anatomic structures for storage and digestion. Specialized anatomic structures limit the kinds of foods which may be eaten by the animal that possesses them. Man is a facultative carnivore and herbivore. He possesses the common enzymes of both species with increased storage capacity over the Carnivora and decreased complexity of stomach and colon over the Herbivora. The upright position assumed by the human species does not in any way hinder, hamper or decrease the digestive efficiency. The digestive system of man as we know it is a fundamental endowment; it is one of the greatest attributes he possesses, and is to a large extent responsible for obtaining his so-called preeminence over all living things. Criticisms of this remarkable system because man assumes the upright position are destructive, founded on false assumptions, and serve no purpose other than to create apprehensions in the minds of those who are unable through lack of training or opportunity to make first hand comparisons of the various digestive systems of mammals.

In considering diets and giving dietary instructions to patients, if the occasion arises, it should be emphasized that man is superior to all other mammals in the number and variety of foods that he may eat and digest, and that the number and variety of foods that he may eat is limited only by his alimentary capacity. However, the possession of these superior digestive qualifications does not warrant abuse. The cellulose of food is largely indigestible. Moderately large amounts of this material may be eaten without producing digestive disorder. The same is true of dirt and other foreign materials, but such practices are not to be sanctioned. Emphasis should always be placed on the fact that the upright position has given man no digestive handicaps. Supposed symptoms attributable to "stasis" and "angulation" of any part of the alimentary canal as a result of the upright position are spurious. In short, man is anatomically and physiologically superior in his digestive functions, the same as he is supposed to be in his intellectual attainments over all living things.

Causes of Mortality Among Diabetics

By

HENRY J. JOHN, M.D.
CLEVELAND, OHIO

WHEN we look upon the mortality tables in such exhaustive studies as those of the Metropolitan Life Insurance Company, Chart 1, we can see clearly that diabetes is practically at the bottom of the column, only 28 cases dying each year in 100,000 population as against 261 dying from the diseases of the heart. But even such a number represents some 35,000 cases of people having diabetes dying each year in this country.

If we consider our population as 125 million and the total number of diabetics in this country as one million, then if no new cases came up, the total diabetic population would die out in 28 years. However, if we consider for the sake of argument, that our diabetic population is at a fairly steady level, d.e. that as many new cases develop as the number that die, then we must reason that there are some 35,000 new cases of diabetes developing each year, an incidence of .028 per cent, which would mean that in a city of one million population there should be some 280 new cases of diabetes each year and also some 280 deaths from the diabetic ranks yearly.

When a diabetic patient dies, the death certificate usually bears as the cause of death the simple statement of "diabetes." This naturally introduces a grave error into our statistical studies as it shows that the mortality rate from diabetes is on the increase, as the extensive studies of the Metropolitan Life Insurance Company seem to indicate. However, is this truly so? Do these patients die *of* diabetes or merely *with* diabetes? I have attempted in this study to analyze the mortality data from my own series of 4744 cases of diabetes of whom 527 died over a period of 15 years, and it is the study of this group of 527 cases which I am here presenting.

Submitted April 14, 1937.

I have put to myself three questions which I shall attempt to answer: 1. At what age do most diabetics die? 2. What is the cause of death in these diabetics? 3. How long have they had their diabetes at the time of death?

THE AGE AT DEATH

Chart 2 presents the distribution of these 527 cases that died, arranged according to the decade of life in which they died. Sixty-nine per cent died in and above the sixth decade and 31 per cent in from the first to the sixth decade. Almost 50 per cent died in the seventh and up decade.

On that same chart I drew a curve of the mortality rate in non-diabetics this strictly speaking includes diabetics, these representing about one per cent, thus an insignificant factor from a large series of 41,233 deaths reported from New York City in 1933 by Bolduan. Curve "a" represents this series and the interesting point is that the curve is practically parallel to my curve of diabetics. This fact alone shows that as far as mortality in diabetics and non-diabetics is concerned, about the same percentage of each die in their respective decades, in other words, diabetes presents no striking difference in the mortality-age-incidence.

In curve "c" I plotted the experience of Bolduan and Weiner in 1272 cases of diabetic deaths and there too,

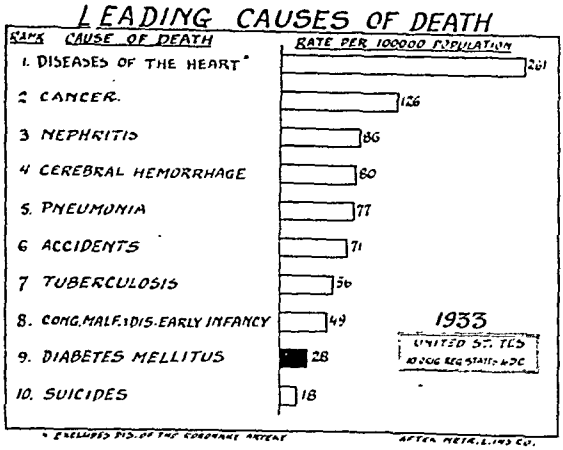

Fig. 1. Leading causes of death in ten original registration states and District of Columbia after Metropolitan Life Insurance Company.

can be seen a curve fairly parallel to mine which, I feel, substantiates these data.

In New York City where nearly one-third of the population is Jewish, Bolduan and Weiner gathered some interesting statistics. In 1931 there were 41,233 total deaths, and of these 14,047 or 34 per cent were Jews, and 27,186 or 66 per cent were non Jewish white. In this same group of deaths the diabetic deaths comprised:

	Jewish	Non-Jewish
	602	670
Per cent of total mortality	4.29	2.45
Per cent of group mortality	4.3	2.4

These figures show that mortality among the diabetics is twice as much among the Jews as it is among Non-Jewish whites with diabetes. This I think is quite a significant figure.

The fact that upward of 50 per cent of people with diabetes die beyond the seventh decade throws the weight of mortality toward the old age, when a mortality is more or less expected even in non-diabetics. Thus one would reason that diabetes here plays a comparatively small role, for the mortality in the early decades is comparatively insignificant. Having crossed half a century of our life line, we have to be prepared for accidents which may and do happen, for the best part of life, as far as duration is concerned, is over.

Thus we can summarize, that those having diabetes as a rule do not die young, but rather toward the other end of the natural life line, in the same relative ratio as the non-diabetic, and we can step up to consider point two.

THE CAUSE OF DEATH IN DIABETES

What is the actual cause of death in diabetics? Chart 3 and Table I present these data. Here the outstanding factor is cardio-renal disease, which again is largely a disease of old age, a degenerative disease. Even if we withdraw the purely renal disease, the uremia, which I placed at the top of the cardia-renal column, the length of the column is still entirely out of proportion to all other causes of death. Blotner, for instance, reports a mortality rate of 45 per cent in coronary occlusion in all cases of diabetes coming to necropsy at Peter Bent Brigham Hospital. In non-diabetics over forty years of age the disease was found in 21 per cent. He says that in 43 per cent of all the series the chief cause of death was directly attributed to cardiac disease. But there are so many things that diabetics can die of, the same as non-diabetics, for diabetes does not carry with it an immunity to other accidents. Hajek points out that fact that arteriosclerosis which in his series of cases in 1920-1921 represented 28 per cent rose to 60 per cent in 1931-1934 as cause of death, where as coma which in the first series was 54 per cent fell off to zero in the last series. If we consider the deaths in my group of 527 cases which are purely due to diabetes, namely coma, we see that the actual percentage as compared with all other causes is comparatively insignificant, comprising but 11.1 per cent of the total mortality. Thus we could say that only 11.1 per cent of all deaths in this group was actually due directly to diabetes. We can go a step further and say that even this per centage could be lower by proper and adequate care, for my figures among children in coma mortality rate were 3.2 per cent, and in adults 5.6 per cent. Thus an average of 4.4 per cent or practically one-third of those in this series which includes cases from my series of diabetics taken care of during coma elsewhere, and

furthermore it dates back into the preinsulin era.

It is evident therefore that patients who have diabetes rarely die of diabetes. They die of something else. We need badly a revision of our mortality statistics in this country, and I dare predict that as our younger generation of physicians go out, with much better training than we older men had, we will see the true mortality rate in diabetes falling. Thus when we watch the rising curve of diabetic mortality gathered by the Metropolitan Life Insurance Company statistics, we have to take it with a bit of reservation. In my estimation the mortality rate due purely to diabetes is not high.

Of course, we can go a step further and reason how much, for instance, does diabetes contribute to the cardio-renal question, the arterio-sclerotic gangrenes, but that is another problem which will require close statistical, X-ray and biochemical studies which will have to cover a period of many years. It is a good project for some younger man to undertake as a life study, a problem which will be very important scientifically and statistically.

DURATION OF DIABETES

How long have these patients who died had diabetes? We can gather this interpretation from Table II, in which I have analyzed this group of 527 deaths among diabetics according to the length of diabetes and their death in the various decades. One needs but consider the data in the column of "average duration of life after they developed diabetes." In this group, the older the person is when he develops diabetes, the longer his life line. We start with 1.24 years in the first decade and wind up with 6 years in the seventh and above decade; thus the span is five times longer when the diabetes develops in advanced years. We speak of the fact that the first year of life following the discovery of diabetes is the most important period. They either make the grade or they do not. After the first year the road is much easier to trod, for by that time the patient has acquired a certain dexterity in the handling of his problem and his chances are better. This accounts largely for the shorter span of life in the earlier years, an inability of one's adapting himself to this new problem.

It is not merely the diabetes itself which is the de-

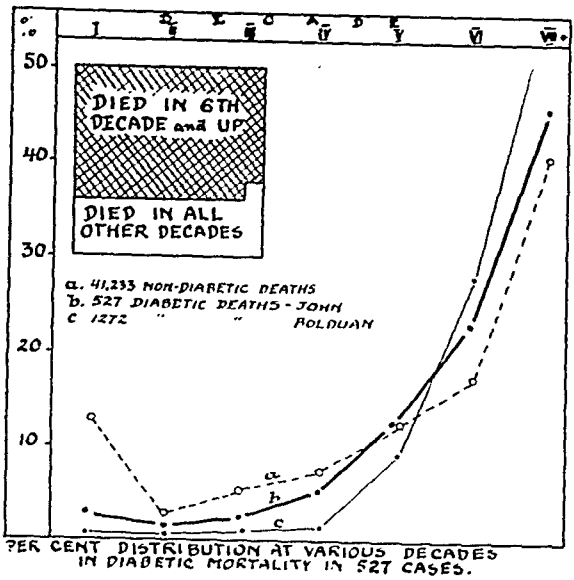

Fig. 2. The per cent distribution at various decades in diabetic mortality in 527 cases.

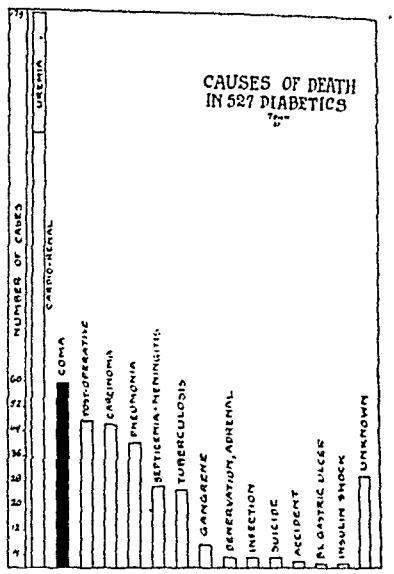

Fig. 3. Causes of death in 527 diabetics.

ciding factor. There are many other factors which enter the question of longevity. Let us take for instance the simple question of obesity which too is quite dominant among the diabetics. Again we shall turn to the large statistics of the Metropolitan Life Insurance Company, a publication by Dublin who shows that the question of mortality per 100,000 arranged according to weight is as follows:

Mortality of those of normal weight	14 per M.
Mortality of those 15-14 % below nor. wt.	9 per M.
Mortality of those 15-34 % below nor. wt.	9 per M.
Mortality of those 5-14 % above nor. wt.	22 per M.
Mortality of those 15-24 % above nor. wt.	45 per M.
Mortality of those 25-up % above nor. wt.	117 per M.

You can readily see how this factor alone would change the pure mortality picture in diabetics if one author reported a series of cases of normal weights or below and another author a series of much over-weight patients. And there are other factors of a similar nature which enter into the picture and which complicate it so that at best, our statistics are somewhat fragmentary.

SUMMARY

This study of rather a small group of cases of diabetics shows clearly enough, I think, that diabetics do not die early in life as a rule, but largely late in life when life is already on the descent; that they do not die because they have diabetes, but largely because of some other condition which can befall any non-diabetic; that the older they are at the time that diabetes develops, the better chance they have for a longer span of life. I wish to emphasize the need for improved mortality statistics.

A Study of Gastric Emptying with the Pylorus Open*

By

J. O. CRIDER, M.D.†

and

J. EARL THOMAS, M.D.‡

PHILADELPHIA, PENNSYLVANIA

THIS research was undertaken to determine if possible whether the delay in gastric emptying known to follow the addition of such substances as HCl, dextrose, fat, etc., to a test meal is the result of "closure of the pylorus" as frequently stated or is due to some other cause. It is a part of a more general study of the mechanism that regulates the emptying of the stomach, in which we have been engaged for a number of years (1, 2, 3).

The usual method of investigating the problem has been to remove the pylorus surgically, and then to determine whether the emptying of various materials from the stomach was hastened, or still proceeded in an orderly manner. This type of experiment was apparently first performed by von Mering (4), who studied dogs after resecting the pylorus and observed that the emptying of water, milk and sugar-peptone solutions from the stomach occurred at intervals as usual and was neither slower nor faster than normal. More recent investigations have given similar results.

Thompson (5) removed the pyloric sphincter along with more or less of the pyloric portion of the stomach in a large series of dogs. In most of the animals the continuity of the tract was re-established by means of a Polya gastrojejunostomy. He was primarily interested in the secretory changes following operation and discussed the effects on emptying time but briefly. We have therefore obtained his permission to report the following private communication (6): "In my observations on the emptying rate of the stomach in dogs after resection of the pyloric sphincter, the results varied with the test meal and the method of observation. Using the opaque meal in roentgenologic studies, the time required for the emptying of the stomach was shortened after operation in 80 per cent of the animals. Using the meat-water meal in fractional analyses, the emptying time after operating was prolonged in 67 per cent of the animals. I attribute this difference to the nature of the test meals used keeping in mind the fact that the meat-water meal is normal and that the barium-acacia-milk meal is not normal for the dog. I conclude therefore that more time is required for the stomach to empty itself of the food in the normal diet following resection of the pyloric sphincter than is required when the sphincter is intact."

These results were probably influenced to some extent by the fact that in most of the operated animals the stomach emptied into the jejunum, instead of the duodenum which is the source of many important regulatory influences affecting gastric motility.

Gianturco (7, 8) studied the effects of gastro-enterostomy and of pyloric excision in cats on the rate of gastric emptying of fat, hypertonic solutions of sugar and salt and of water. He observed "hardly any difference" between the emptying times after the operations and those of normal cats. "We were forced to conclude," he says, "that the pylorus is not responsible for delayed emptying of oils and concentrated solutions of salt and sugar."

Chrysler and Van Liere (9) found that sectioning the pyloric sphincter, gastro-enterostomy, or partial parasympathetic denervation of the pyloric sphincter in dogs did not decrease the gastric emptying time. Ravdin (10) observed that the amount of glucose solution remaining in the stomach after one hour was not reduced following gastro-enterostomy, Polya or Billroth I operations. Ravdin, Pendergrass, Johnston and Hodes (11) performed similar experiments using oils, protein and hypertonic glucose solutions as well as water barium mixtures, and found that operations designed to eliminate the restraining function of the pylorus did not hasten the emptying.

Pyloric resections, gastro-enterostomies and similar operations on patients should provide an abundance of material for studies of pyloric function in man, but little exact information is recorded. More or less signficant studies have been reported by Gaither (12), Kirschner (13), and Beresow and Stern (14), all indicating that, except in occasional instances, the operations referred to do not hasten the emptying of the human stomach. Beresow and Stern studied 25 cases after Billroth I operations and found very rapid (blitzartige) emptying in three. In five others the emptying was somewhat accelerated but orderly; in the remainder it was normal. Somewhat different results were reported by Shay and Gershon-Cohen (15), who found that in the cases reported fats and solutions of different osmotic pressures did not delay gastric emptying to the same degree in stomachs with resected pylorus as in the intact stomach. Since they were dealing with achlorhydric patients, their results do not provide a basis for generalization.

Best and Taylor (16) state that, "X-ray examinations of the stomachs of patients in whom the pylorus has been excised, show emptying times which do not differ appreciably from the normal (Singleton)." Dr. Singleton (17) advises us that the statement refers to unpublished observations made in "the examination of a number of cases who had Billroth I operation for duodenal ulcer, cases in which the pyloric sphincter and the duodenal caput only were excised and end-to-end gastro-duodenostomy performed. These cases obviously have no sphincter left, in spite of which the emptying time of their stomachs was within normal limits." Dr. Singleton further points out the

impossibility of obtaining normal controls in such cases, because of the pathologic state existing prior to the operation.

In the absence of opposing data, it is reasonable to conclude that pyloric resection or other operations with a similar functional significance do not shorten the *total emptying time* of the normal stomach of man or of certain experimental animals. However, when the *rate* of emptying during the first few minutes after feeding is observed, the results are somewhat different. Cannon and Blake (18) found that after pyloroplasty (in cats) the exit of carbohydrate and protein food from the stomach began earlier and progressed somewhat more rapidly than in normal animals. McCann (19) observed that in a dog after resection of the sphincter more of a meal consisting of meat and water had passed into the intestine in twenty-five minutes than was noted at the same period of digestion in a normal animal. Pannett (20) found that after pyloroplasty (in cats) food passed into the duodenum and jejunum more quickly during the early stages of digestion than in normal cats. He could not affirm, however, that the accelerated passage was maintained during the later stages of digestion.

The investigations reported, although they are significant, fall short of furnishing a final solution of our problem. Gastro-intestinal operations may, for various reasons, be followed by delayed gastric emptying which would conceal the effect of loss of pyloric function. Removal of the pyloric sphincter may not abolish the sphincteric function, which may, conceivably, be assumed by adjacent rings of antral muscle. Meyer and Schmidt (21) consider the possibility of a sphincter-like action of the muscle surrounding any gastro-intestinal anastomosis. There is the further difficulty in operative experiments that the control observations and the experimental studies must be separated by a considerable time interval during which the characteristic emptying time may change.

METHOD

The method of study that we have used provides for eliminating the sphincteric function of the pylorus without interrupting the continuity of the gastro-intestinal tract. It provides also a means of determining whether the sphincteric function is, in fact, absent and of making con-

trol and experimental observations on alternate occasions.

Dogs were used, provided with gastric and duodenal fistulas in a manner described in detail elsewhere (2). The fistulas were fitted with stoppered cannulas of hard rubber; after healing was complete, the tendency to leakage was well controlled. Such animals live indefinitely, barring accidents to the cannulas, and show no nutritive disturbances traceable to the fistula operations. The gastric fistula was placed near the greater curvature in the body of the stomach, well away from the pyloric antrum. The duodenal fistula was between six and eight inches from the pylorus. Both fistulas were so placed in the abdominal wall as to bring about a minimal displacement of the viscera.

To measure the emptying time, the test material was allowed to flow into the empty stomach through a tube passed through the stopper in the gastric cannula. The entire contents were then withdrawn at appropriate intervals through the same tube into a graduated cylinder, the quantity noted, and the material returned to the stomach. The "emptying time" was recorded as the time required for the stomach to reduce its content to 50 c.c. or less. All the materials were liquid and were at room temperature when placed in the stomach.

Because of the occasional presence in the "empty" stomach of various amounts of gastric juice, food residues, hair, etc., which tended to cause variations in emptying rates, we adopted the practice of washing out the stomach and duodenum with water and filling the stomach with 300 c.c. of saline, which was permitted to remain until emptied normally before beginning observations. The emptying time of this "washing out" saline was not recorded; it was observed and, if it was unusual, observations were postponed until the saline emptying time returned to within normal limits.

To eliminate the sphincteric function of the pylorus, an open aluminum tube was placed in the pyloric orifice and held in place by means of pieces of rubber tubing attached to its two ends and brought out through the stoppers in the cannulas (Fig. 1). The gastric contents were free to enter the lumen of the aluminum tube through four ¼" holes near its gastric end and to pass into the duodenum through holes in the wall of the rubber tube attached to the duodenal end. The outer ends of the rubber tubes were closed with clamps. It was possible to demonstrate the patency of the pylorus by opening the outer end of the duodenal tube and draining out the entire contents of the stomach through the tube in the pylorus. The material flowed in a steady stream the full diameter of the tube and was all out in less than one minute. By this procedure occasional accidents, such as plugging of the tube with mucus, displacement of the apparatus, etc., were readily detected, and we are confident that the pylorus was actually open throughout the experiments that are so recorded.

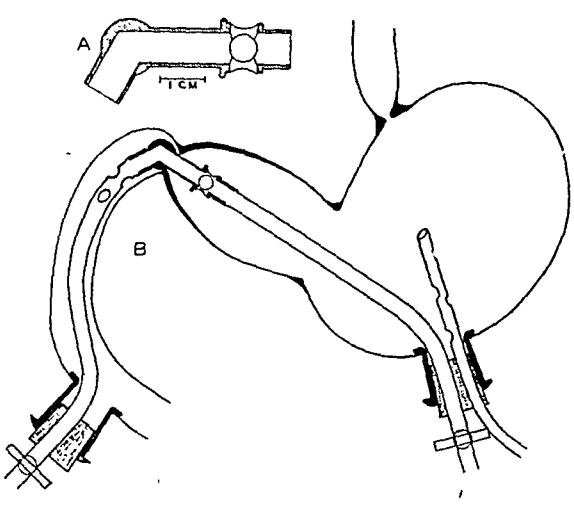

Fig. 1. Diagram of apparatus used to keep the pylorus open. Insert (A) is a scale drawing of a section through the pyloric tube. The gastric contents passed through the lumen of this tube and therefore encountered no resistance due to the pylorus. An apparatus of identical shape and dimensions but without holes in the gastric end was used in approximately half of the control experiments (dummy controls); in these the gastric contents necessarily passed between the outer surface of the tube and the pyloric sphincter.

Three types of experiments were performed with each of the materials investigated: (1) normal controls to determine the emptying time in the absence of any apparatus, (2) dummy controls with an apparatus in the pylorus identical externally to the open pyloric tube but without holes, and (3) experiments with the open tube in place (pylorus open).

SOURCES OF ERROR

The animals were abnormal in that they had gastric and duodenal fistulas. There is no evidence that the emptying times were influenced by this fact, but we do not present the normal controls as measurements of the normal emptying time for the materials studied. The frequent emptying and refilling of the stomach also may have influenced the emptying time. These and other important conditions were the same in all the experiments and could not have determined the difference or lack of difference in emptying times observed in the experiments with the pylorus open as compared to the controls.

The most serious objection to the method is the necessity for placing apparatus, tubes, etc., in the stomach and duodenum. This difficulty was partially overcome by control experiments with the dummy apparatus in position so that whatever irritation the apparatus might cause would have an equal opportunity to affect the control results. However, it is evident that the dummy apparatus tended to obstruct the pylorus and thus introduce a condition not present in any of the other experiments. This difficulty was evident during approximately the first thirty minutes after placing the apparatus; after that time it did not appear to influence the results. Whatever influence it may have had would have been opposite to the general trend of the results and may therefore be disregarded.

RESULTS

The emptying times of the stomach for 300 c.c. 0.9 per cent sodium chloride solution, N/20 hydrochloric acid, olive oil (100 c.c. plus 200 c.c. of normal saline), 5 per cent glucose solution and 10 per cent ethyl alcohol in normal saline were studied. The N/20 HCl was prepared in approximately isotonic solution by mixing equal parts of N/10 acid and normal saline. Normal controls, dummy controls and experiments with the pylorus open were recorded for each substance. The average emptying times as well as the amounts remaining in the stomach after 10 and 25 minutes (for olive oil after 30 minutes and three hours) are shown in Table I. The number of experiments of each type is shown in parenthesis beside the averages.

The average emptying times, except for olive oil, were not significantly influenced by the different experimental conditions. Keeping the pylorus open did not accelerate the emptying of any of the substances investigated. The partial obstruction of the pylorus with the dummy apparatus also failed to alter the emptying time. There was a consistent, and probably

significant, delay in the emptying of oil when the pylorus was open as compared to the controls.

In Fig. 2 the average amounts of the various substances remaining in the stomach at regular intervals after filling are shown graphically. These curves give an idea of the rate of emptying during the various phases of the emptying process. Each of the curves except the dummy control curves for alcohol was plotted from the averages of all the results obtained under the stated conditions with both animals. In one animal the emptying of alcohol with the dummy apparatus in place was unaccountably rapid; for this reason the dummy control experiments with alcohol were plotted separately for the two animals. With this exception and again with the exception of olive oil the average

the emptying of acid is regulated by means of a reflex mechanism having a short latent period and therefore fully operative from the beginning, whereas the emptying of glucose is controlled by a humoral mechanism with a relatively long latent period which would permit rapid initial emptying. Whatever the regulating mechanism may be, it is evident that its essential characteristics as they affect the curves were not materially modified by keeping the pylorus open.

To determine whether the stimuli that controlled the emptying in these experiments acted within the stomach or only in the intestine, additional experiments were performed in which the duodenum was drained. The dummy apparatus was used because it provided a convenient means of anchoring a drainage

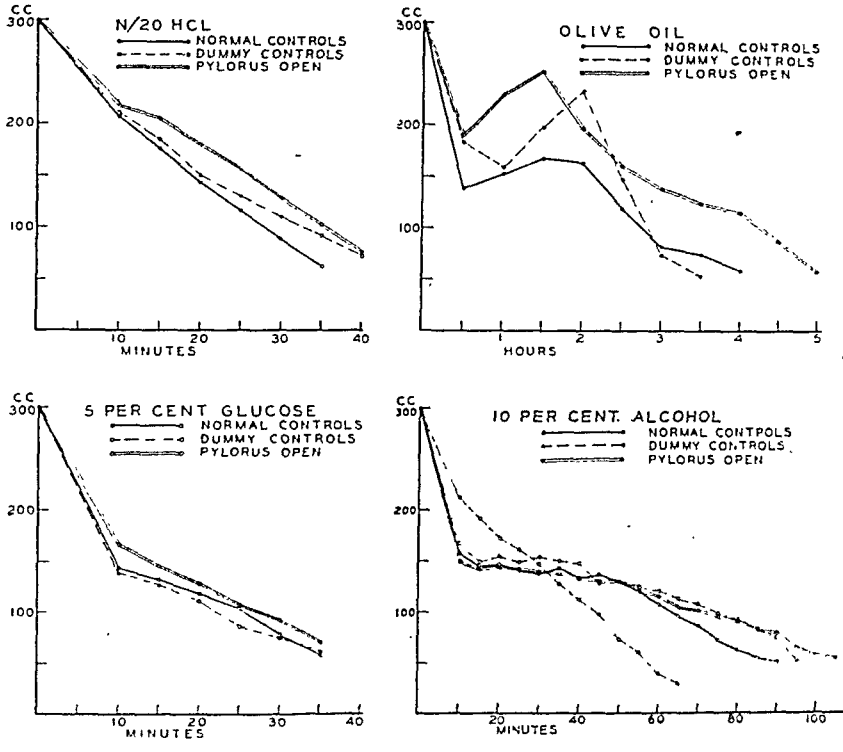

Fig. 2. Curves showing the rate of exit of various materials from the stomach under different experimental conditions. Ordinates represent the amounts remaining in the stomach, abscissas the elapsed time after filling. With certain exceptions mentioned in the text, the data were obtained by averaging the results of all the experiments of each kind on two animals.

rate of emptying at any time was not significantly affected by the experimental conditions. There is no evidence in these results that the initial emptying was accelerated by keeping the pylorus open. The delay in the emptying of olive oil when the pylorus was kept open was evident during all phases of the emptying process.

The emptying curve has a characteristic appearance for each substance, suggesting differences in their effect on the mechanism for regulating emptying. For example, the rate of emptying of acid was fairly uniform, the corresponding curve tending to approximate a straight line; the emptying of glucose was rapid during the first ten minutes and then became slower. These results may be explained by the assumption that

tube within the duodenum. The rubber tube attached to the duodenal end of this apparatus was perforated with a number of large holes so placed as to be as near the pylorus as possible. A rather long drainage tube was used, so that when it became filled with fluid a negative pressure of about 30 cm. of water was maintained within its lumen at the upper end. The pylorus was functioning. The gastric contents emptied around the apparatus and drained to the outside without coming in contact with more than a small part of the duodenal mucosa.

Under these conditions 300 c.c. of normal saline left the stomach in an average time of four minutes for one animal and 6.5 minutes for the other. The average emptying times of N/20 HCl were five and eleven

minutes for the two animals respectively; for olive oil they were eight and 15 minutes. If anything went wrong with the drainage—for example if the negative pressure was not maintained—the emptying of oil was much delayed. In one experiment, in which the appearance of bile in the drain tube indicated that some oil was free in the duodenum, there was no appreciable emptying of oil from the stomach for more than one hour.

Considering the fact that contact of the material with the intestinal mucosa could not be prevented completely even by drainage under negative pressure, we think that the slight differences in emptying time recorded with the duodenum draining can be disregarded, and the conclusion maintained that the differences in emptying time observed under normal conditions were entirely the result of stimuli acting within the intestine.

The experiments with duodenal drainage show that even normal saline has some effect within the intestine, tending to delay the emptying of the stomach, since duodenal drainage reduced the saline emptying time to about one-fourth of that required normally.

Certain incidental observations seem worth recording. Bile was found at some time in the gastric contents regularly after alcohol, acid or olive oil had been given. This was true whether or not the pylorus was able to function. It appeared earlier and in greater abundance when the pylorus was kept open. The greatest amount of regurgitation occurred after oil, and the next greatest after alcohol. With both substances there were frequent increases in the amount of the gastric contents. We got the impression that the normal mechanism of fat digestion may involve the passage of the fat into the duodenum to be mixed with the digestive secretions and its later return to the stomach for storage during the process of digestion.

In the beginning we attempted to use Wesson oil as a fatty substance. We were unable to do so because the animals consistently vomited the Wesson oil, although they tolerated equal amounts of olive oil fairly well. The olive oil was occasionally vomited—more frequently when the pylorus was kept open.

In the experiments with alcohol, the animals presented gross evidence of intoxication only when the stomach emptied rapidly. We infer from this that the rapid absorption of dilute alcohol, such as to produce intoxication, takes place from the intestine rather than the stomach.

In one animal the rapid passage of alcohol into the duodenum brought on fits of sneezing. We have noted a similar reaction in another animal in which any mechanical irritation of the duodenum caused sneezing.

DISCUSSION

The stomach can empty only when its contents are subjected to a force sufficient to overcome the resistance to their passage into the duodenum. The force is provided by peristalsis in the antrum or increase in the tone of the gastric muscle as a whole, and takes the form of pressure on the contents, especially in the region of the pylorus. The resistance encountered is due either to the narrow pylorus or to back pressure from within the duodenum, and is determined quantitatively by the activity of the sphincter or the duodenal muscle respectively. There are therefore three mechanisms available for the regulation of gastric emptying, either separately or in combination: (1) variations in the tone or the peristaltic activity of the gastric muscle; (2) opening and closing of the pylorus; (3) variations in the activity of the duodenal muscle. Which of the three is most important in the regulation of gastric emptying under normal circumstances remains undecided, although there has been in the past a tendency to center attention on the pylorus.

The results here reported, which are in accord with the evidence available from the literature, demonstrate that the pylorus is not an esential part of the mechanism that regulates the emptying of certain liquids, including some believed to be of the greatest importance normally as stimuli for the regulatory mechanism.

Our results do not show an acceleration of the initial emptying rate with the pylorus open, although such a change appears to be a constant result of surgical removal of the pylorus. This difference may be due to the fact that the first observation in each of our experiments was made too late to detect the more rapid initial emptying when it occurred. It is more probably an indication that the materials which we used contained nothing capable of retarding initial emptying, so that this phase was comparatively rapid even in the controls. Any delay in initial emptying is evidently due to stimuli which act within the stomach. In selecting our materials for investigation, we chose those which are thought to delay evacuation only when present in the duodenum or other part of the intestine. It is in regard to the significance of the effect on the pylorus of duodenal stimulation that there has been the greatest difference of opinion.

The actual cause of the slower emptying from the stomach of such substances as we used can, perhaps, be determined by measuring simultaneously the intragastric pressure, pressure within the duodenum, and pyloric tone. We have done some experiments along this line which we hope to report at a later time. At present we can say that the function that we have found to vary most consistently with the rate of emptying is antral peristalsis.

The greater delay in the emptying of fat when the pylorus was kept open, as compared to the control experiments, appeared to us to be due to more frequent and extensive regurgitation from the duodenum under these conditions. A similar factor was probably operative in the experiments with alcohol, although it was not great enough to produce an unequivocal difference in the average emptying times; it is slightly suggested also in the results of experiments with acid. Probably one important function of the pylorus is to control duodenal regurgitation. The powerful pyloric contraction which follows each gastric peristaltic wave and coincides in time with an increase in duodenal activity (22) is strongly suggestive of such a function.

Our results show that the gastric contents, though liquid, will not leave the stomach even through a wide open outlet except at a certain rate characteristic for the substance concerned. Therefore the pylorus is not necessary to keep the stomach from "leaking" when its contents are fluid. This fact supports the conception of intra-abdominal mechanics set forth by Cannon (23, 18). He explained that the full stomach is essentially in the situation of a bag full of water suspended in water and will, therefore, not empty by simple drainage due to gravity.

SUMMARY

The emptying time of the dog's stomach for normal saline, isotonic glucose solution, N/20 HCl, 10 per cent alcohol or olive oil was not shortened by the presence of a device which kept the pylorus continuously open.

The rate of emptying of these substances was not accelerated in any observed phase of the emptying process by keeping the pylorus open.

The exit of olive oil from the stomach was retarded throughout the period of emptying and the emptying time prolonged when the pylorus was kept open.

An open pylorus favors regurgitation from the duodenum.

CONCLUSIONS

Closure of the pylorus is not an essential factor in the delayed emptying from the stomach of oil, acid solutions and certain other liquids. One function of the pylorus is to control duodenal regurgitation.

Duodenal Intussusception*

By

W. W. BOARDMAN, M.D.

and

EMERY LEIVERS, M.D.

SAN FRANCISCO, CALIFORNIA

DUODENAL intussusception occurs so infrequently that in most textbooks it is not mentioned and Fitzwilliams (1) in his report of one thousand cases of intussusception found no case originating in the duodenum. He further states that "the duodenum, on account of its fixity, is never the starting point of the trouble." However, Kellogg (2) in his excellent book, "The Duodenum," devotes a chapter to duodenal intussusception and reports eleven cases gathered from the literature during the past hundred years. Of these, five originated in the stomach, thus leaving only six of true duodenal intussusception.

After a careful search of the literature we have been unable to find any additional cases. Because of the infrequency of the lesion, the diagnostic problems presented, and its amenability to treatment, we have felt justified in briefly reviewing the earlier cases and in reporting a recent case from the Stanford Medical Service.

CASE REPORTS

Case I: 1830. K. Sundelin (3). Male, aged 47. Always well up to six months before admission. During this period he was troubled with intermittent attacks of severe abdominal pain associated with vomiting. His last attack started after a heavy meal with pains in the lower addomen followed by vomiting. The pains increased in severity, the vomiting persisted, and became "coffee-ground-like," he was thirsty, the extremities were cold, the face was livid, the pulse was rapid and feeble, and there was hyperaesthesia of the abdomen. Autopsy revealed an intussusception of almost the entire length of the duodenum into the jejunum. Directly above the invagination, the duodenum was seen constricted for about two-thirds of its diameter by a smooth solid induration.

Case II: 1866. V. Paris (4). Male, aged 25. About ten months before his fatal illness, he began to notice a heavy feeling in the epigastrium which had no relation to meals. This symptom continued and about five months later was associated with vomiting. Vomitus was not remarkable. Attacks occurred three or four times per week. The patient was not incapacitated. Constipation progressively increased. Nine months later, the attacks increased in frequency and duration. He entered the hospital because of pain and vomiting. On entry, he had no fever, was pale and emaciated, but in no extreme distress. There was pain in the epigastrium and left hypochondrium. His attacks continued irregularly for a period of weeks. He had no relief, became very weak, and died of pulmonary complications. Autopsy revealed a partial invagination of the terminal portion of the duodenum into itself. Only one portion of the circumference of the duodenal wall was invaginated. A fibro-muscular polyp was found which had this portion of the wall for its base.

Case III: 1896. W. Collier (5). Male, aged 21. His illness began about twelve months previous to his admission with pain across the upper abdomen and vomiting. These symptoms increased in severity during the last six months. The pain was not affected by food and the vomitus was not remarkable. On entry, the patient looked anxious

TABLE I

Summary of the findings in the seven cases of duodenal intussusception

Case	Age	Sex	Symptoms and Signs						Laboratory Findings			Treatment	Outcome	Pathological Report
			Duration	Vomiting	Pain	Weakness	Weight Loss	Tumor	Anemia	Blood in Stool	X-ray			
1	47	M	6 mos.	+	+	+						Medical	Died	Constricted duodenum
2	25	M	10 mos.	+	+	+						Medical	Died	Fibromyoma for polypus
3	21	M	12 mos.	+	+			+				Surgical	Died	Polypi
4	75	F											Cadaver	Fibroadenoma
5	69	M	4 mos.	+	0	+	+		+	+	Dilation of duodenum and upper jejunum	Surgical	Recovered	Benign adenoma
6	58	M	12 mos.	+	+	+		0		+	Dilated duodenum	Medical	Died	Mucus adenoma
7	62	F	9 mos.	+	0	+	+	+	+	+		Surgical	Recovered	Papilloma

and decidedly ill. Nothing was discovered in the abdomen to account for the pain and vomiting. His symptoms continued relentlessly under conservative regimen. One evening, the patient was seized with more severe abdominal pain and urgent vomiting. Later, a distinct mass could be made out, running obliquely across the abdomen from left to right. Surgery was advised with the tentative diagnosis of intussusception. A large insussusception was found commencing within a few inches of the pylorus. The invagination was easily reduced but his condition did not improve. On postmortem examination an enormous number of polypi were found. These varied in size from a pigeon's egg to a pea and were scattered throughout the stomach and the small intestines with the greatest number in the duodenum and the upper jejunum. The specimen showed a large lobulated villous growth situated in the duodenum a short distance from the pylorus. The constricted attachment of this villous growth to the mucous membrane was the starting point of the intussusception.

Case IV: 1897. P. Thompson (6). Female cadaver, aged 75. The author states, "I was able to ascertain that for some months before death there had been no gastric disturbance and no symptoms to lead one to suspect the presence of the growth." The cause of death was certified as "senile decay." Examination of the intussusception revealed that the pylorus and the first part of the duodenum had passed into the second part of the duodenum and formed a prominent mass from which the pedicle of the tumor projected. The tumor pedicle originated from the inferior margin of the pyloric ring. Microscopic diagnosis of the tumor was "fibroadenoma."

Case V: 1926. E. L. Kellogg (7). Male, aged 69. Family and past history were non-contributory. For the past four years, he had noted periods of fullness and flatulence but no marked symptoms until August, 1926. At that time, he had a sudden attack of nausea and vomiting followed by severe cramp-like pain, lasting ten to twenty minutes and recurring at frequent intervals for twenty-four hours, located below the navel and extending across the abdomen. The symptoms disappeared after three days and he remained well until October, 1926, when he vomited repeatedly without pain. Later in the same month there was slight fever for three days and for two days the bowels did not move. This was followed by a gradual loss of weight and strength and progressive anemia. In November, following an attack of vomiting with marked prostration, he was admitted to the Polyclinic Hospital. He was moderately nourished but very anemic. The pulse was rapid and feeble, there was slight tenderness to pressure about the navel, and the bowels moved with anemata. Roentgen-ray investigation showed dilatation of the duodenum and upper jejunum. This was attributed to adhesions causing obstruction. The stools contained occult blood. At operation, the upper portion of the jejunum was distended, dark, and contained a solid oval mass which was movable within the lumen. This was pushed upward through the jejunum and the duodenum until it presented at the pylorus but could not be forced past the pyloric ring. It was readily delivered through an incision crossing the pylorus at right angles and proved to be a pedunculated tumor attached to the posterior duodenal wall close to the pyloric ring. The tumor was removed and the wound closed without drainage.

It was determined that the superior duodenal angle had been obliterated by stretching of the hepatoduodenal ligament, and that an intussusception of the duodenum and pyloric end of the stomach into the jejunum had taken place without causing complete obstruction.

Pathologist's report: Tumor from the duodenum: adenoma, benign.

Follow-up reports indicated that within about six weeks his blood picture was practically normal. He was rapidly gaining weight. Three years later he was in good health.

Case VI: 1929. L. Muller (8). Male bartender, aged 58. Patient entered the clinic with the symptoms of pyloric stenosis with gastric dilatation which was thought to be the result of a cancer or ulcerated cicatrix. For the past

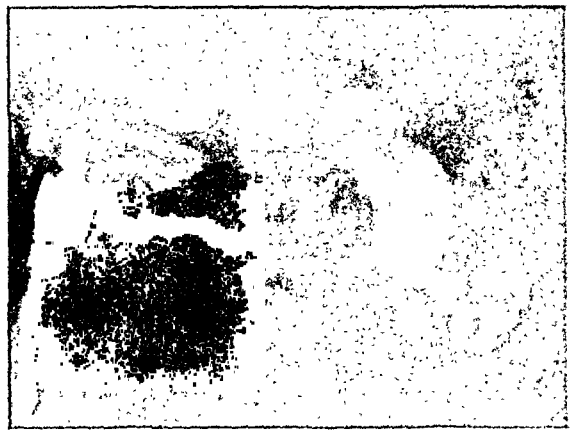

Fig. 1. Case VII. Barium examination showing dilated duodenum with cone-shaped distal end.

Fig. 2. Case VII. Barium examination at three and one-half hours; stomach and duodenum still filled with barium.

year, he had experienced frequent vomiting and severe thirst. The vomitus was usually of a mucous nature. Four weeks before hospital entry, pain appeared in the right side. He vomited after each meal and complained of anorexia, weakness, and frequent fainting spells. His urine volume was small. He had no fever. He continued working until eight days previous to admission.

On physical examination, he appeared extremely emaciated and vomited frequently. The vomitus was bloody mucus with no fermented odor. No masses were felt in the abdomen. Benzidine reaction in the stool was triple plus. On the second day, he had a little muscle spasm but nothing definite could be made out to explain his complaint. Patient failed rapidly and died on the third day.

At autopsy, the stomach was in its usual position. About four finger-breadths below the pylorus near the superior duodenal angle a five-centimeter piece of the upper outer circumference of the duodenal wall disappeared into a funnel-like lumen. At the apex was found a walnut-shaped soft, purple polyp which was covered with fine villi. The polyp was rich with blood but was not ulcerated or hemorrhagic. Nothing remarkable was found in the rest of the duodenum except adhesions between it and the liver capsule. The jejunum was enlarged twice its normal size for the first meter portion. In the enlarged portion, there were two more invaginations; one, about a hands-breadth below the duodeno-jejunal junction and the other twenty-five centimeters further down. The former was isoperistaltic and circular and the latter was antiperistaltic and retrograde. The ileal contents were of a black, tarry-like nature.

Histological examination: The polyp was a mucous adenoma of papillary character.

Case VII: Stanford. 1936. Mrs. B. T. Female, aged 62. Entered Stanford Hospital August 28, 1935, stating she had been perfectly well up to December, 1934, at which time she began to be troubled with nausea and vomiting, the latter coming on fifteen minutes to two hours after meals. She felt that in the last six months she had vomited practically all the food eaten. Her weight had dropped from two hundred to ninety-six pounds at the time of admission. For several weeks before admission the vomitus had been coffee-ground-like in character, there had been extreme weakness, there had been no pain, and stools had been tarry.

The family and past history was unimportant.

Physical examination, made by a student at time of admission, was unimportant except for the evidence of emaciation and the presence of a large mass in the epigastrium. Later, examination by the medical house officer, failed to confirm the presence of this mass. A few days later, the mass was again described about fifteen by ten centimeters in the epigastrium to the right of the midline. It was noted that this mass could be pushed across the midline.

A blood count showed 3,750,000 red cells with a hemoglobin of 67%; white and differential count was unimportant.

A urinalysis was negative.

A histamine test-meal showed a maximum total acidity of twenty-four; free hydrochloric of eight; a strong occult blood reaction, highest ten minute volume was twenty-five cubic centimeters.

An icterus index was fifteen.

Stool examination was strongly positive for blood.

Blood Wassermann was negative.

A gastro-intestinal X-ray series on August twenty-ninth was first reported to show no demonstrable disease of the gastro-intestinal tract. After further consultation with the X-ray department, the following report was given: "Preliminary film of the abdomen shows no abnormal small or large bowel gas. No calcified or soft tumors are seen. Examination of the stomach with barium shows a normal appearing stomach. Peristaltic waves travel to the end of the stomach. The duodenal cap fills completely. Barium gets into the duodenum but at the immediate examination no barium at all passed through the duodenal loop. The obstructed end of the duodenum is cone-shaped. The patient was seen again in three and one-half hours at which time the barium was still in the stomach, and in the duodenal loop. Only a tiny amount of barium had passed into the jejunum. At twenty-four hours, the stomach and small bowel were empty. *Conclusion:* Obstruction in the duodenum. This was complete for a few hours but later the obstruction was apparently relieved for at the twenty-four hour examination the stomach and duodenal loop were both empty."

On September third, examinations made by Dr. A. L. Bloomfield who was unable to feel any abdominal mass. The following day, patient had slight fever and swelling of the left parotid. Vomiting persisted. Dr. E. Holman was called in in surgical consultation at which time no abdominal mass was palpated. Diagnosis was deferred. Patient kept up symptomatic treatment. On September eighth, patient was again seen by Dr. Bloomfield who reported "the whole situation is still obscure, tongue is definitely smooth, abdomen is very soft, and I am still unable to feel any mass. The story of poor diet may be related to the present anemia and glossitis."

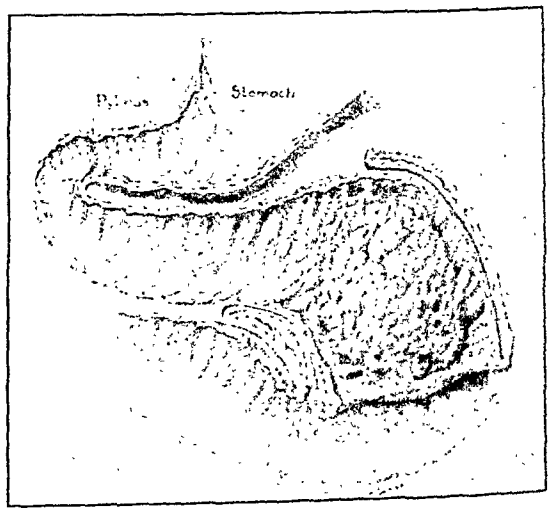

Fig. 3. Case VII. Drawing showing the papilloma in the duodenum and the intussusception.

is generally thought to be stasis of bile with secondary infection playing a minor role. The diagnosis of gall bladder disease depends primarily upon roentgenologic findings. This will reveal failure of the gall bladder to concentrate the dye, failure of the dye to reach the gall bladder, or a deficient secretion of bile, all of which will show non-visualization of the gall bladder.

The author believes that the treatment should attempt to relieve bile stasis. In accordance with this, one of the authors began giving a diet of cream, butter and in some cases eggs, plus frequent feedings of high smooth bulk together with antispasmodics. Cooked fats or greases were curtailed. During the last three years keto-cholanic acids were also used. The author believes that this method results in a direct stimulation to the flow of liver bile and also initiates contraction of the gall bladder.

The results of this therapy on 131 patients showed that those receiving the keto-cholanic acids were improved greatly both subjectively and objectively, except in those cases where large stones were demonstrated. These cases, however, showed marked subjective improvement. The authors conclude that this is the therapy of choice in low grade gall bladder disease, but that it should not be used in common duct obstruction and acute cholecystitis.

Francis D. Murphy, Milwaukee.

SCHINDLER, RUDOLF, ORTMAYER, MARIE AND RENSHAW, JOHN F.

Chronic Gastritis. J. A. M. A., Vol. 108, p. 465, Feb. 6, 1937.

Chronic inflammation of the stomach, although not considered an entity for the past thirty years, has recently been shown to exist. Clinically chronic gastritis was rediscovered with gastroscopy by the senior author in 1922. The normal mucosa has been studied in people of all ages and has been found to be smooth, silk-like, glistening and orange red.

In 2500 patients with abdominal complaints who were examined gastroscopically, 50 per cent present evidence of mucosal changes characterized by layers of whitish, grayish or greenish mucus, or hyperemic spots. These were termed superficial gastritis and usually healed. Other cases showed greenish gray spots which did not change and were termed atrophic gastritis. In still others, the mucous membrane was swollen, thickened, velvety, often containing hemorrhages, and erosions and nodules, nodes, creases or crevasses. This was termed hypertrophic gastritis and in spite of careful treatment would not return to normal. The fourth type occurs postoperatively, consists of all other three forms combined and has the worst prognosis.

In a study of 228 cases at the University of Chicago, it was found that the age varied from twenty to sixty years. The duration of symptoms averaged five and one-half years. The hypertrophic form was commonest in the male, the other forms equally distributed. In some cases appetite was poor, in others normal. The distress was epigastric, delayed in the hypertrophic form, and occurring shortly after meals in the atrophic form. Periodicity was present in some of the hypertrophic forms, but not as marked as in ulcer. Many had gas and belching.

In all forms the intestinal function was normal.

Physical examination was usually negative. In some cases there is a tender zone on light palpation below and to the left of the navel. Gastric analysis is practically useless. X-ray examination also is of little help in diagnosis. Gastroscopy is the only diagnostic procedure at present.

The treatment consists of a very bland diet, fed in frequent small amounts. Raw fruits and vegetables must be avoided. Bed rest for eight days and hot applications should be used in the superficial form. Lavages

AN IMPORTANT FACTOR

The intestinal tract, in the opinion of many authorities, constitutes one of the most important factors in systemic disease. So frequently is it the focus of infection that it can no longer be overlooked in the etiology of many systemic disorders, allergic and otherwise.

When symptoms point definitely to the absorption of toxic substances from the intestinal tract, consider the value of Soricin (sodium ricinoleate) as a detoxifying agent. Soricin inhibits putrefaction and proteolysis, and tends to reduce toxicity of the bowel content.

Thus, the absorption of toxic substances from the bowel—evidenced by such, frequently remote, symptoms as migraine, vertigo, and urticaria—can be checked in many cases by the oral administration of Soricin.

TWO DOSAGE FORMS

Soricin Capsules: (Enteric Coated)

10 grain size, available in boxes of 20 and 100 capsules each.

5 grain size, available in boxes of 40 and 100 capsules each.

Soricin Tablets: (Enteric Coated)

5 grain size, available in bottles of 100 tablets.

CINCINNATI, U. S. A.

the lumen, giving rise to slowly developing obstruction."

It would thus seem difficult to differentiate the symptoms arising from primary tumor with obstruction from those arising from tumor complicated by intussusception, except that the symptoms of obstruction from tumor would probably be more constant than those from intussusception. An evanescent mass is probably the most typical finding. Treatment is obviously surgical and should be successful if complications are not encountered. Naturally, the earlier the diagnosis is established and treatment undertaken, the better the prognosis. The post-operative course in the Stanford case was extremely difficult because of the deficiency states.

CONCLUSIONS

1. True duodenal intussusception does occur but is a rare lesion.
2. It is usually secondary to a benign tumor of the duodenum.
3. It may occur in males or females and from twenty-one to seventy-five years.
4. Vomiting, emaciation, anemia, evanescent epigastric mass, and X-ray evidence of dilatation of the duodenum are the usual findings.
5. Surgical treatment should be successful if complications are not encountered.

A Study of Peptic Activity by Means of the Double Histamine Test

By

ANDREW B. RIVERS, M.D.*

and

FRANCES R. VANZANT, M.D.†

ROCHESTER, MINNESOTA

IT is not our intention to review in detail the voluminous literature on the secretion of pepsin or its rôle in the etiology and chronicity of peptic ulcer, except to state that values for pepsin are usually increased in the presence of peptic ulcer. There also is much evidence to suggest that ulcers heal with great difficulty in a medium of gastric chyme which has an increased peptic concentration. There can scarcely be any doubt that some relationship exists between persistently accentuated peptic activity and accentuated ulcer-forming tendencies in certain cases. In a previous paper we have shown that a remarkable degree of correlation exists between the amount of ferment and the severity and intractability of the symptoms.

Recently, we have made some investigations regarding the behavior of the chief cells and the parietal cells during the course of a double histamine test, which consists of the study of the secretion following two successive injections of histamine. The object of this study was to learn more about the ability of the cells to maintain vigorous secretory rates. We were interested not only in learning how high a concentration of acid and pepsin could be attained but we wanted to know how long the acid-pepsin secretion would be continued before retardation of these rates became evident, for we believed that both the intensity and the duration of the secretory response might serve as a means of determining the accentuated ulcer-producing tendencies in certain cases.

The controversy regarding the ability of histamine to stimulate the secretion of pepsin continues. Most observers have noted an increase in peptic activity of the gastric juice shortly after the injection of histamine, but many have assumed that this is due solely to a washing out of preformed pepsin and that it is not the result of actual stimulation of the parietal cells.

Some interesting facts regarding the behavior of the parietal cells during the course of the double histamine test were observed. These suggested that stimulation of the parietal cells by histamine results in a copious outflow of pepsin from the tubules in much greater amounts than could be expected from a simple washing-out process.

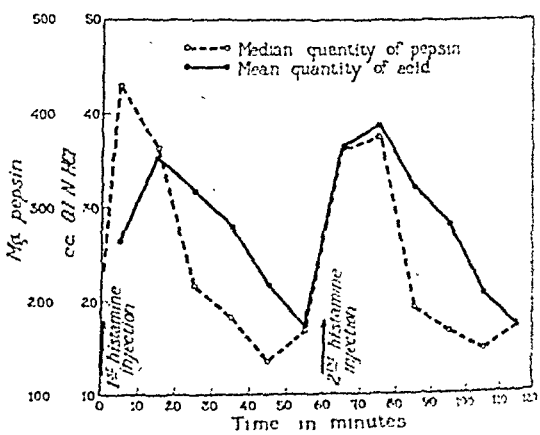

Fig. 1. Change in the secretion of pepsin and gastric acid following the injection of histamine; one may note a marked rise in the secretion of both constituents following the second injection.

Submitted March 17, 1937.

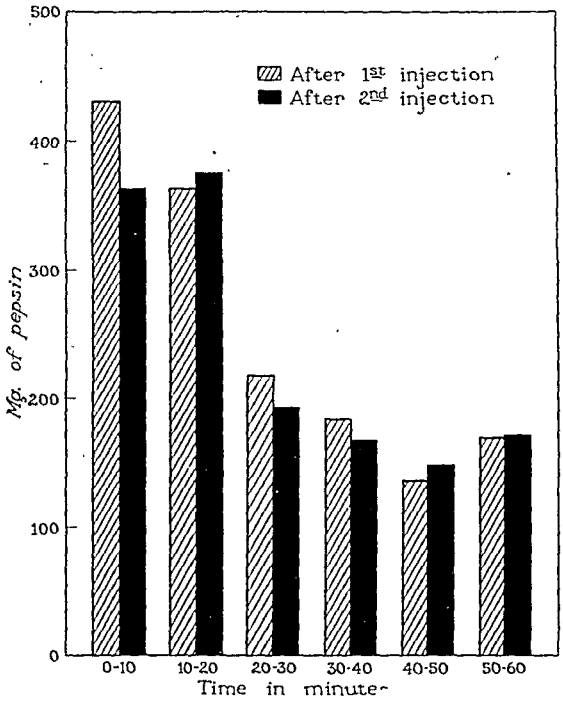

Fig. 2. Comparison of increase in the secretion of pepsin following first injection of histamine and that following a second injection; the increase produced by the second injection is equal to that produced by the first.

METHOD OF STUDY

In performing double histamine tests a small-bore Sawyer tube was introduced into the stomach and the gastric contents were aspirated as completely as possible. The contents then were evacuated at ten-minute periods during which time unstimulated fasting secretion was removed. After collecting two or three fasting specimens and assuring ourselves that the stomach was free of secretion, histamine was injected subcutaneously in doses of 0.1 mg. for each 10 kg. of body weight. Following this, gastric juice was aspirated for six periods of ten minutes each. Then the same amount of histamine was again injected subcutaneously and specimens were collected for six more periods of ten minutes each. The concentration of pepsin was estimated by the modification of the Gilman-Cowgill method described by Osterberg, Vanzant and Alvarez and acidity was determined by titration with tenth normal solution of sodium hydroxide, using Töpfer's reagent as an indicator. Figures representing quantities of acid and pepsin secreted for each period of ten minutes were obtained by multiplying the concentration of the substances by the volume of the specimen.

RESULTS

This test was performed in sixty-six cases. In a large number of these cases the patients had peptic ulcer. Table I shows the concentration and quantity of the pepsin secreted during the successive ten-minute periods.

From a study of the results obtained in these cases it is evident that the argument, that the secretion of pepsin is not stimulated by histamine but that preformed pepsin is merely washed out, breaks down because the shortness of the interval between the two injections precludes the possibility of pepsin accumulating in the tubules in as large a quantity as we obtained following the second injection of histamine. The curves (Figs. 1 and 2) show that the secretion of pepsin reaches its height in the first twenty minutes after injection and then falls rather abruptly to a low level. Following the second injection of histamine, an almost identical curve was observed except that

TABLE I

The mean and median concentration and quantities of acid and pepsin secreted by sixty-six patients

Time after first dose of histamine, minutes	Free hydrochloric acid				Pepsin

60 Second dose of histamine	59.4	62.7	17.3	11.9	880	650	141	169
70	72.6	74.0	36.4	26.2	1297	1032	382	363
80	85.5	92.9	38.7	34.4	1220	930	400	375
90	85.7	86.7	32.1	28.0	954	750	242	192
100	79.5	83.0	28.0	22.3	847	660	219	167
110	66.4	71.7	20.6	16.3	824	640	182	147
120	62.8	64.3	17.0	12.4	970	836	178	171

slightly higher values for pepsin were obtained in the first ten minutes after the first injection than were obtained in the corresponding period after the second injection. This difference may well be due to a washing out of preformed pepsin by the first injection.

SUMMARY

It would seem that histamine performs two functions so far as the presence of pepsin in the stomach is concerned: First, it causes a washing out of the preformed pepsin and, second, it stimulates an actual secretory increase in the function of the parietal cells.

The Effect of the Oral Administration of Bile Salts on the Composition of Human Fistula Bile*

By

K. G. KOHLSTAEDT, M.D.

and

O. M. HELMER, Ph.D.

INDIANAPOLIS, INDIANA

THE enterohepatic circulation of bile acids as postulated by Schiff (1) in 1870 has since been confirmed and proved conclusively by the work of numerous other investigators (2, 3). Although the changes occurring in the enteric portion of this circulation are well known, the intrahepatic mechanism has remained an unknown factor. However, by observing the changes in the chemical composition of the bile, it is possible to determine the end results of the bile acid metabolism as it is effected by both the endogenous and exogenous factors involved in the enterohepatic circulation of bile salts.

Whipple and his coworkers (4) have carried out careful and extensive studies on bile acid metabolism in the dog. These workers have shown that the limiting factor in the output of bile acids is the amount of available cholic acid. Although the precursors of cholic acid are as yet not definitely known, Whipple and Smith (5) have shown that tryptophane is essential for the formation of cholic acid.

In the dog Whipple (4) has also observed the importance of diet. The lowest output of bile acids occurred in animals which received only carbohydrates. The output of bile acids was lower on this diet than in the fasting dogs, the reason being that there was less destruction of body protein in the animals on a carbohydrate diet than in the fasting dogs. The highest output was obtained with a meat diet which supplied ample proteins. In the fasting dog the output of bile acid remained at a constant level for a considerable length of time, and this fixed level is called the "endogenous level" (4) of the bile acids. However, Whipple obtained the maximum output of bile acids by bile salt feeding in these dogs. Furthermore, these experiments have demonstrated that there is a regulatory mechanism present in the liver which controls the secretion as well as the destruction of bile acids. The greatest stimulation of this hepatic secretory mechanism can be produced by the administration of bile salts.

Very few similar determinations of the bile salt metabolism have been carried out on human bile. Recently Doubilet (6) has described improved methods for bile salt analysis which are applicable to human bile. We wish to present a series of cases in which we have attempted to determine the components of human bile as they exist in fistula bile obtained from cases of postcholecystostomy and choledochostomy, and further, to observe the changes that can be produced in the composition of that bile by the oral administration of bile salts.

METHODS

The constituents of the fistula bile and the methods used for their determination are as follows: cholic, desoxycholic, and taurocholic acids by the methods of Doubilet (6); total conjugated bile acids by the method of Smith, Groth and Whipple (7); and cholesterol by the method of Elman and Taussig (8).

The human fistula bile used for the following differential chemical analyses was obtained from ten patients who had been operated for some pathology of the biliary tract. In some cases the drainage tubes were placed in the gall bladder and in the remaining cases "T" tubes were placed in the common bile duct. The specimens were collected for periods of 24 hours, and aliquot portions were used for analysis.

All patients were given the same type of diet postoperatively. However, in those patients with severe postoperative nausea and vomiting, the entire diet was not taken and this would cause some variation in the rate of secretion of bile acids.

The hippuric acid test was used to determine the degree of hepatic damage and the serum bilirubin was used to measure the degree of icterus.

Five patients who were used as controls did not receive any bile salts either preoperatively or postoperatively. The remaining five did receive bile salts* during the postoperative period of study.

DISCUSSION AND RESULTS

The first four cases presented in Table I form a control group in that they did not receive any bile salts and they all received the same type of diet, although an accurate record of the food intake was not kept.

In Case 1 the collection of bile was begun immediately after surgery, but in Case 2 the collection of specimens was not started until the eleventh day after surgery. Together these cases present a complete daily analysis of human choledochal bile over a period of 17 days. The results indicate that the composition of this bile and the proportion of each component studied in the 24 hour specimens is remarkably uniform in spite of the variable diet. Similar results have been reported by Whipple and Smith (9) in their analyses made on dog bile under similar conditions.

In Cases 1 and 2 and in other cases of this series the output of conjugated bile acids, as determined by the *amino-nitrogen method*, was often found to be larger than the output of total bile acids as determined by the iron method. Similar results were also observed by Doubilet (10) in his postoperative fistula cases. His explanation of this is that the fistula bile may contain other amino-nitrogenous materials which are soluble in alcohol thereby increasing the concentration of the conjugated acids above that of the total bile acids.

The bile cholesterol output in these cases was similar to the amount found in fistula bile by Wilkinson (11).

The third case in the group differs from other cases in that there was a higher proportion of desoxycholic acid, although the amount of cholic acid and cholesterol was at the same level observed in the first two cases. The conjugated forms of bile acids were not determined in this case. On the fourth day there was a sudden and unexplainable rise in the desoxycholic content of the bile, while in the other cases this immediate postoperative period was characterized by a decreased output of all bile acids and cholesterol. However, this rise was of short duration so that on the eleventh day the amount of desoxycholic acid present in the bile approached the amount found in the other control cases. The cholic acid and cholesterol content followed the same course as outlined in the first two cases.

The fourth case in this group was that of a cholecystic fistula and the specimens were obtained on the second and the sixth days. The composition of the bile in these specimens was the same as that observed on the same days in other cases of this control group.

The fifth case demonstrates the changes which occur early in the course of "hepatic insufficiency." The specimen of the first 24 hour period after surgery showed a level of bile acids and cholesterol similar to that found in the other cases in the first postoperative specimen. In the second and third specimens there was a very rapid decline in the concentration of these substances in the bile. This decrease in the quantitative secretion of bile acids and cholesterol was not paralleled by a proportionate decrease in the volume of bile obtained from the fistula. The volume of the first specimen was 153 c.c.; the second was 660 c.c.; and the third was 163 c.c. The patient died a few hours after the third specimen was obtained.

Smyth and Whipple (12) have observed a similar phenomenum in dogs. When the dog was given a small dose of a hepatotoxic drug such as chloroform, it was possible to reduce the bile acid content of the bile to within 10 per cent of normal without decreasing the flow of bile. Furthermore, it was found that there was no change in the microscopic appearance of the liver cell in the dogs which had received this dose of chloroform although there had been a marked change in the metabolic function of the liver cell. Bollman and Mann (13) have been able to produce the opposite result in dogs by means of toluylenediamine. After

the administration of this substance to dogs, a marked suppression of the flow of bile occurred, but a rise in the bile acid content of the peripheral blood and urine indicated that there had not been an equal depression of the bile acid formation by the liver. These results would indicate that the formation of the bile acids by the hepatic cell is not merely a mechanical filtration of these substances from the portal blood but rather is a distinct metabolic function of the liver cell.

The four cases presented in Table II received bile salts during the postoperative period. The first case in this table (Case 6) received bile salts from the third to the fourteenth day. The administration of bile salts produced a marked increase in the amount of cholic acid and desoxycholic acid and in the amount of bile acids conjugated with glycine, but there was no definite change in the amount conjugated with taurine or in the amount of cholesterol contained in these specimens of bile. The increase in bile acid elimination occurred in the first 24 hour specimen after administration of the bile salts, and the bile acid content was maintained at this high level for the remainder of the period of observation. This level was distinctly higher than any observed in the control cases during a similar period of observation.

At the time of operation of Case 7, sufficient bile was found in the gall bladder to permit a complete analysis of this bile. These results are given in Table II. This patient had received bile salts for 1 month prior to operation, but this medication had been discontinued for 10 days before surgery. This sample of gall bladder bile differed from the fistula bile studied in that the bile acid content was very much higher and this increase was confined chiefly to the desoxycholic acid fraction and the portion conjugated with glycine. Taurine and cholic acid and cholesterol were not increased above the amount found in the fistula bile in the same case after surgery. There was also a large amount of free bile acid present in this specimen. This relative reduction of the cholic acid content and the presence of free bile acid was observed by Doubilet (10) in gall bladder bile from cases of cholecystitis. Doubilet considers these findings significant of cholecystitis and he is of the opinion that the inflamed gall bladder is unable to absorb the desoxycholic and the free bile acid. The pathological report of the gall bladder obtained from Case 7 showed a definite chronic cholecystitis. The cholesterol content of the gall bladder bile was not increased above the amount found in the fistula bile.

Further study of the specimens of fistula bile obtained from Case 7 after the choledochostomy revealed a marked decrease in the bile acid content during the first 48 hours after surgery. This depression of bile acid secretion was observed during the immediate postoperative period in the other cases in this study, and Greene, Aldrich and Rowntree (14) have observed the same decrease in bile acid output in the dog after a cholecystectomy under iso-amyl ethyl barbituric acid narcosis. This depressant effect of surgery of the extrahepatic biliary system may have been due to the operative procedure itself, the anesthetic, or a disturbance in the portal circulation.

The administration of bile salts was started in Case 7 during the first 24 hours after surgery, and the output of bile acids promptly rose to a level above that observed in the control cases. The cholic acid showed less response than the desoxycholic acid to the oral administration of bile salts. During the eleventh day there was a very great increase in the amount of desoxycholic acid secreted. Again, as in all of the other

cases, the cholesterol and taurine fractions were only slightly affected by the bile salt administration.

In the two remaining cases in this table the bile salts were not started until much later in the post-operative period. The decrease in the bile acid and cholesterol content of the bile during the first few days after surgery was very evident in these cases (Cases 8 and 9). In both patients the composition of the fistula bile prior to the administration of bile salts was very similar to that observed in the control cases presented in Table I. The bile salts produced a rise in the cholic, desoxycholic, and bile acids conjugated with glycine, but produced no definite change in the acids conjugated with taurine or in the cholesterol output.

Case 8 differed from all others in this study in that all specimens of the bile contained free bile acid, while in the other cases free bile acid was found only occasionally.

Case 10 is presented in Table III. In this patient the pathology was found to be intrahepatic rather than extrahepatic. Grossly, at the time of operation, the liver presented the typical picture of a severe hepatitis. It was possible in this instance to measure the exact amount of food taken by the patient. The stools were examined for urobilin and bile salts. The urine was tested for bile salts and the degree of icterus was followed by means of the serum bilirubin test.

The patient's condition was critical for the first 8 days after surgery and it was doubtful if he would survive. Several transfusions were necessary as well as intravenous glucose solution during the first portion of the postoperative period. When the collection of bile was begun on the eighth day it was impossible to detect any cholic acid, desoxycholic acid, or cholesterol in the bile. Some taurine was found, but a portion of this may have been due to the presence of ethereal sulphates or sulphur compounds in the bile other than taurine. It is of interest that this patient was able to survive with the hepatic function at such a very low ebb for 12 days. These results are similar to those reported by Ravdin and his associates (15), who found that bile salts were always absent in the liver bile after the common duct had been completely obstructed for a week or more and that their reappearance occurred only after a considerable time. Furthermore, Greene, Walters, and Frederickson (16) observed that in cases with hepatic injury due to biliary cirrhosis there was a delayed reappearance of bile salts and they had not reached normal at the end of the period of observation.

Again, as in Case 5, the volume of bile did not parallel the secretion of bile acids and cholesterol. Since very little bile entered the intestinal tract during the first part of the postoperative period, the volume of bile obtained from the fistula represents a fairly accurate measure of the total bile volume. Furthermore, during this period there were no bile salts found in the urine and there was also a rise in the serum bili-

rubin which would indicate a very marked suppression of the activity of the liver cell.

Cholic acid first appeared in the specimen obtained during the 24 hours in which the administration of bile salts was started. The bile salt content rose rapidly to the level found in the control cases, but the cholesterol content of the bile did not increase to the same degree. It would appear that in this case the liver was unable to form cholic acid from the precursors present in the body, but that it was able to secrete this substance into the bile when it was supplied to the hepatic cell by the portal blood from an exogenous source.

The increase in the volume of the bile obtained from the fistula in Case 10 demonstrated that the bile salts are cholagogic as well as choleretic.

The increased elimination of bile salts was followed by a decrease in the serum bilirubin which was indicative of improvement of the pigment metabolism. Along with these changes there was a marked rise in the caloric intake and all of these changes were reflected in the clinical improvement observed at this time in the patient. The patient gained strength; his mental state improved; he was more alert and interested in his surroundings.

The maximum concentration of bile acid in this bile was obtained with a dose of 3 gm. of the bile salts per day. When this dose was increased to 4 gm., the stool specimens became positive for bile salts and a digestive upset occurred in the patient. However, this maximum output of bile acids did not equal the maximum concentration of bile acids observed in other cases in which there was no evidence of intrahepatic pathology. The degree of hepatic damage in this case is shown by the fact that the hippuric acid test, taken at the end of the period of study when the greatest amount of liver regeneration should have been present, revealed a detoxifying ability of only 50 per cent of normal. It is therefore probable that other hepatic mechanisms had not reached normal at this time.

SUMMARY AND CONCLUSIONS

1. In each case the composition of the human fistula bile was found to be remarkably constant in spite of a variable diet.

2. A marked increase in the concentration of the bile acids in this fistula bile was produced by the oral administration of bile salts. The increase in the bile acids was not accompanied by a proportionate increase in the cholesterol content of the bile. It was therefore possible by the oral use of bile salts to alter the bile salt-cholesterol ratio of the bile secreted by the liver.

3. The portion of the bile acids conjugated with taurine was not increased to the same level as the other bile acids present in this fistula bile.

4. Following surgery of the extrahepatic biliary system there was a short period of decreased bile acid secretion. This period of depressed activity was accentuated by hepatic damage.

5. The bile volume did not parallel the rate of excretion of bile acids and cholesterol.

CASE REPORTS

Case 1. A. D., a white female, age 65, had had typical attacks of gall bladder colic over a period of 19 years accompanied by a definite intolerance for fat and fried foods. There was no history of jaundice during or following an attack. All laboratory studies were normal at the time of admission. Cholecystogram revealed a non-visualized gall bladder. The patient was operated on October 22, 1936, and a cholecystectomy and choledochostomy were performed. Several faceted gall stones were removed and the gall bladder showed evidence of chronic cholecystitis. No choledochal stones were found. The postoperative course was uneventful. No vomiting occurred after the first day and the patient was given the usual postoperative diet. The collection of bile from the catheter in the common bile duct was begun as soon as the patient returned from surgery and was continued until the tube was removed 10 days later.

Case 2. H. P., a white female, age 50, who had had several previous attacks of gall bladder colic, was admitted to the hospital because of jaundice which had occurred following an attack of pain. The onset of the present attack had begun suddenly 3 weeks prior to admission. Serum bilirubin was 5 mg. per cent at the time of admission. Three days later the patient was operated and a stone was removed from the common bile duct. A rubber catheter was placed in the duct. There was a moderate postoperative reaction following this surgery, but the patient's temperature was normal on the third day and there was no vomiting. The remainder of the postoperative course was entirely uneventful. The collection of bile was not begun until the eleventh day, and this was continued until the seventeenth day. During this time the patient was on the routine hospital diet. The patient did not receive any bile salts during period of hospitalization.

Case 3. M. W., a white female, age 59, was admitted to the hospital and operated as a case of ruptured appendix. The onset of the present attack occurred two days prior to admission with severe pain along the right infracostal margin with subscapular radiation. The pain had been present continuously since the onset and had increased in severity. There had been no nausea or vomiting. Although the patient had had intolerance for fat and fried foods, there had been no definite attacks of gall bladder colic.

The patient gave history of an arrested case of pulmonary tuberculosis and had had eleven pregnancies with one miscarriage. When the abdomen was opened, an acutely inflamed hemorrhagic gall bladder was found. One large gall stone was removed. The gall bladder was not removed and a simple cholecystostomy was done. The specimens of bile were collected from the drainage tube placed in the gall bladder. Biliary drainage was collected from the first to the eleventh postoperative day. The patient did not receive any bile salts during the preoperative or postoperative period.

Case 4. E. F., a white female, age 62, was admitted to the hospital during an acute attack of pain in the right upper quadrant, which had been present for five days accompanied by nausea and vomiting. The patient gave a history of similar attacks over a period of two years. There was no history of jaundice and there was no definite food intolerance. The patient had had typhoid fever twenty

years ago. She had had nine pregnancies. On admission the oral temperature was 101° F. and the white blood cell count was 17,000.

The patient was taken to surgery as an emergency. The appendix was found to be normal, but the gall bladder was acutely inflamed and gangrenous, with a stone wedged in the cystic duct. A cholecystostomy was done and the bile was collected from the tube placed in the gall bladder. The postoperative course was very stormy and the patient ran a high temperature with a marked degree of abdominal distention. Drainage from the tube in the gall bladder stopped on the seventh day, but there was profuse biliary drainage from the wound around the tube. The convalescence was long and she regained her strength slowly. No bile salts were given.

Case 5. F. G., a white female, age 52, was admitted during an attack of gall bladder colic. She complained of severe epigastric pain and at the time of admission a slight degree of icterus was visible (serum bilirubin 2.1 mg.). Cholecystogram revealed an opaque biliary calculus with nonvisualization of the gall bladder. Six weeks after admission, when the serum bilirubin had decreased to 1 mg., the patient was operated. Due to numerous dense adhesions the surgery was extremely difficult, and a stone could be removed from the common bile duct only by a transduodenal approach. A catheter was placed in the common duct. The postoperative period was very stormy. The patient died on the third day with a hyperpyrexia and rapid pulse. The death was a typical "liver death" due to combined hepatorenal failure. Specimens of bile were obtained from the catheter in the common duct at 24 hour intervals. No bile salts were given either preoperatively or postoperatively.

Case 6. G. S., a white female, age 38, had had pain in the upper right quadrant without subscapular radiation for 3 months prior to her admission. There was no history of food intolerance, previous attacks of gall bladder colic, or visible jaundice.

At the time of admission, a smooth, movable mass, which was very tender, had been palpated in the gall bladder area. The patient was seen by both the urological and gynecological services in consultation, and on July 29, 1936, an exploratory laparotomy was performed. The mass in the abdomen was found to be an enormously distended gall bladder with a stone impacted in the cystic duct. A choledochostomy was done along with the cholecystectomy.

No bile salts had been given preoperatively, but on the fourth postoperative day 'Bilron' (Iron Bile Salts, Lilly) was begun. Twenty-four hour specimens of bile were collected for a period of 14 days. The regular postoperative dietary regime was followed and recovery was uneventful.

Case 7. M. S., a white female, age 28, had been under observation at irregular intervals in the Out-Patient Department of the Indianapolis City Hospital since 1927. During this period she had had several attacks of gall bladder colic. The pain had shown definite subscapular radiation and there was residual tenderness over the gall bladder area after an attack of pain. However, the patient did not give a history of any visible jaundice or fever either during or after an attack. A marked degree of food intolerance and constipation had been present for several years prior to the first attack of pain. In view of this typical history and a positive cholecystogram, which was made in January, 1936, a diagnosis of cholelithiasis was made, but because the patient was only one month postpartum, she was given a trial period on a medical regime which consisted of a low cholesterol, low carbohydrate diet and the use of bile salts. The patient remained symptom free for 27 days, but at the end of this period had another attack of gall bladder colic. Since the patient was now two months postpartum, surgery was advised, and on March 21, 1936, she was admitted to the Indianapolis City Hospital.

Hippuric acid test for liver function was done at this time and 2.58 gm. of benzoic acid were recovered from the urine with a urea clearance of 85 per cent. The serum bilirubin was .8 mg. 100 c.c. and the blood cholesterol was 133 mg. 100 c.c.

Nine days later a cholecystostomy was performed and the gall bladder was found to contain several faceted gall stones and a large amount of dark concentrated bile, which was aspirated for analysis. Twenty-four hour specimens were collected from the drainage tube which had been placed in the gall bladder.

As soon as possible after surgery 'Bilron' was started. For the first two days 1 gm. was given daily and then the dose was increased to 2 gm. Vomiting did not occur after the first day. The entire postoperative course was uneventful, and the drainage tube was withdrawn on the tenth postoperative day.

Case 8. K. S., a white female, age 52, was admitted to the Indianapolis City Hospital on May 16, 1936, during an acute attack of upper right quadrant pain accompanied by chills, fever and jaundice. This attack had begun two weeks prior to admission as a sudden sharp pain in the epigastrium which had been followed by nausea and vomiting. The jaundice had become definitely visible, and at the time of admission the serum bilirubin was 10 mg. and was of the obstructive type.

This patient had had a long series of similar attacks of gall bladder colic prior to a cholecystectomy in 1930. After the cholecystectomy the patient had continued to have digestive symptoms, chiefly food intolerance and constipation, interspersed with an occasional attack of upper right quadrant pain. On one other occasion the patient had become jaundiced during an attack of pain.

Examination revealed an area of tenderness in the gall bladder region with some muscular rigidity. There were no other physical findings. A hippuric acid test with a four hour excretion of 2.21 gm. of benzoic acid (urea clearance 49 per cent) and a galactose tolerance of 2.17 gm. of galactose excreted in 4 hours, would indicate a fair degree of hepatic function. Furthermore, the serum bilirubin decreased rapidly from 10.7 mg. to 3 mg. per 100 c.c. and on June 1, 1936, an exploratory laparotomy was performed. A small common duct stone and amorphous debris were removed from the common bile duct and a rubber catheter was placed in this duct. Twenty-four hour specimens of bile were collected from this tube. The postoperative reaction in this patient was very severe and for several days the temperature was very high and vomiting occurred. However, by the fourth day the temperature had reached normal and the remainder of the postoperative course was uneventful. 'Bilron' was begun on the tenth day postoperatively and continued until the tube was removed from this duct on the thirteenth day.

Case 9. A. S., a white female, age 53, was admitted to the Indianapolis City Hospital on April 15, 1936, with a diagnosis of acute cholecystitis. The patient had had severe upper right quadrant pain for 3 weeks prior to her admission and there was definite tenderness present and a mass was palpable in the gall bladder area when the patient was first seen in the hospital. The pain in this instance was not accompanied by jaundice, but nausea and vomiting did occur frequently. Likewise, a history of intolerance for fat or fried foods with constipation was not given. In fact, the patient had never had any abdominal pain prior to onset of the present attack.

The patient was operated after the acute attack had subsided, and when the abdomen was opened, a bulbous gall bladder was not removed, but a rubber tube was placed in each tract and these tubes were connected by means of a Y tube with a container. Twenty-four hour specimens of bile were collected for analysis. The convalescence was entirely uneventful. 'Bilron' was begun on the fifth day postoperatively and 1 gm. was given daily until the tubes were removed from the gall bladder.

Case 10. O. T., a white male, age 56, was admitted to the Indianapolis City Hospital on August 1, 1936, because of a painless jaundice which had been present for 3 weeks. With the exception of a mild degree of nausea and vomiting and itching, the patient had had no other symptoms since the appearance of the jaundice. The patient had been aware of a loss of strength during the past several years, but there was no definite loss of weight. The patient had never had an attack of gall bladder colic, nor had he shown any symptoms of a cholecystitis. In March of 1936 the patient had had a basal cell carcinoma removed from the right cheek in the preauricular area. This was a typical rodent ulcer. This wound had healed and there was no evidence of extension at time of present illness.

After admission there was no elevation either of temperature or the white blood count. The jaundice continued to increase until the serum bilirubin reached 10.9 mg. per 100 c.c., but after large amounts of intravenous glucose, the serum bilirubin gradually declined until in 3 weeks it had reached 3.5 mg. At this time an exploratory laparotomy was performed, because it was believed that there was an obstruction of the common bile duct due to some malignant growth in the head of the pancreas. However, on exploration, there was no obstruction found in any of the extrahepatic biliary system, although a small discrete tumor was found in the head of the pancreas. This tumor was not believed to be malignant and was so located that it could not have caused an obstruction of the common duct. The gall bladder was removed, but no stones were found, and the cholecystitis was of a mild chronic nature. The liver appeared swollen and edematous and somewhat darker than usual. The cause of the jaundice was not believed to be an obstruction of the intrahepatic biliary ducts. A rubber T tube was placed in the common duct and the collection of bile was begun.

The immediate postoperative course was very stormy. The patient had a high temperature for several days, was given one blood transfusion and several injections intravenously of 10 per cent glucose solution. By the eighth day his condition had improved sufficiently so that he was able to take some food and was not vomiting. The serum bilirubin had increased after surgery until on the eighth day it was 4.7 mg. The differential analysis of the fistula bile was begun on the eighth day and continued for the next 20 days. The administration of 2 gm. of 'Bilron' was started on the eleventh day. There was no vomiting or other untoward symptoms and the patient showed a marked clinical improvement after the bile salts were started. He gained strength; his appetite improved; and, in general, he seemed brighter and more alert mentally. The dose of 'Bilron' was gradually increased until the patient was receiving 4 gm. daily.

The exact intake of food was recorded during the period of observation. Frequent determinations of the serum bilirubin, urinary urobilinogen, urobilin in stools, and bile salts in the stools were made.

On the 39th postoperative day the T tube was closed, and, since no jaundice developed after a period of 2 weeks, the tube was removed. The fistula closed rapidly and the patient was released from the hospital on the 60th postoperative day.

Just before the patient was released from the hospital a hippuric acid test for liver function was determined and the output of benzoic acid in 4 hours was 1.88 gm. with a urea clearance of 88 per cent. This would indicate that, although all evidence of jaundice had disappeared, there was still a marked impairment of the hepatic function.

Gastroscopy as a Diagnostic Procedure*

By

E. B. FREEMAN, M.D.

BALTIMORE, MARYLAND

SINCE the introduction of the Wolf-Schindler flexible gastroscope four years ago, gastroscopy has become a well recognized diagnostic procedure. For many years prior to the development of the flexible instrument, a number of different types of rigid gastroscopes had been tried, and discarded on the basis that the information thus obtained was not of sufficient value to justify the risk incurred. With the advent of the flexible gastroscope, the danger of the procedure was practically overcome, and the diagnostic importance of this type of gastroscopic examination was fully established. The flexible gastroscope is a closed instrument and can be used only for diagnostic study, but with it, almost the entire surface of the stomach may be brought into view. This is not possible with the rigid open tube instrument.

THE RIGID GASTROSCOPE

The rigid open gastroscope however, still has a definite place in the diagnostic study of lesions in the cardiac end of the stomach, and in the management of foreign bodies lodged in the stomach. When the lesion infringes upon the cardia, not only may the lesion be brought into view with the open tube gastroscope, but this type of instrument provides the only means by which a specimen may be removed for microscopic study, thus enabling one many times to make a correct diagnosis. We have had seven cases of carcinoma of the cardiac end of the stomach in which the diagnosis had not been made by routine studies, but was easily made with the open tube gastroscope. The rigid open tube gastroscope is of the utmost value in the management of foreign bodies in the stomach. In most instances in which the foreign body will not pass through the pylorus, it can be removed through the open tube gastroscope, providing of course, the instrument is in the hands of one properly trained for such work, and the necessary X-ray equipment is available. Under no other circumstances should the gastroscopic removal of a foreign body from the stomach be attempted—the risk is too great, and the attempt will usually meet with utter failure.

THE FLEXIBLE GASTROSCOPE

The introduction of the flexible gastroscope is accomplished without much difficulty. However, great care should be observed in introducing the instrument into the esophagus, especially when it passes the cricoid level. This is the narrowest portion of the esopha-

*Read before the National Society for the Advancement of Gastroenterology, Oct. 2nd, 1936.

Submitted March 22, 1937.

gus, and is the location where trauma and perforation are most likely to occur. When the instrument passes this level, no further difficulty is likely to be encountered except a momentary delay at the cardia. With the instrument in the stomach, the most important landmark is the angulus. This comes into the field of vision as a fold coming off from the lesser curvature. Sometimes, as Schindler has stated, it has the appearance of a twisted cord which stands out in a very characteristic manner. With the angulus located, a slight increase in the depth of the instrument should, and usually will, bring the antrum into full view. The pylorus is readily seen in the majority of cases *through*, or as one might say, *at the depth* of the antrum. With the patient in the gastroscopic position, the mucous lake, which is nothing more than a collection of mucus and other gastric secretions in the most dependent portion of the stomach, is another landmark which is helpful in some cases in localizing the portion of the stomach that is under observation, but it is of very minor importance as compared with the angulus.

After some experience in gastroscopic examinations, the appearance of the area under observation is sufficient to give one a very definite idea as to the portion of the stomach being studied. The mucous membrane along the lesser curvature is always quite smooth, and never shows any folds. This smooth appearance of the mucosa is not noted in any other portion of the stomach. Both the anterior and posterior walls are thrown into folds, the general direction of which is towards the pylorus. The folds on the anterior wall are quite shallow and run parallel to the longitudinal diameter of the stomach, converging into the antrum. The folds on the posterior wall and on the greater curvature are quite deep and broad when compared with those on the anterior wall; they too, converge towards the antrum, and fade out somewhat and become less marked as the antrum is approached.

The gastric image is influenced by the change in the position of the stomach due to respiratory movements, by the position of the patient on the examining table, and by the peristaltic activity of the stomach itself. The change in the position of the stomach due to respiratory movements may interfere somewhat with the gastroscopic image, but we do not believe that this change is sufficient to be of any great moment in preventing one from obtaining a clear visual field. A faulty position of the patient on the examining table materially interferes with clear vision. This may either be due to a faulty position of the head, a faulty position of the body, or both. Otherwise expressed, if the patient is not in the proper position on the examining table, a clear visual field cannot be obtained. We have frequently noticed that when an examination is prolonged and the patient becomes somewhat tired, distortion of the visual field may occur, due to the patient assuming a faulty position. It is therefore, quite important not to continue the examination longer than absolutely necessary to actually make a careful study of the stomach wall. This usually requires only a very few minutes.

PERISTALSIS

Peristaltic activity of the stomach is constantly changing the appearance of the visual field, especially in the antral and pre-antral zones. When the antrum is free from peristaltic activity, it is seen as an oval or almost round opening three-quarters of an inch or more in its longest diameter, in the depth of which the pylorus is readily seen. When a peristaltic wave passes over the pre-antral area and approaches the antrum, the entrance to the antrum appears as a mere slit. As the wave passes over the antrum toward the pylorus, the entrance to the antrum is again clearly seen. When the wave actually passes over the pylorus, the pylorus will be seen to close, and the mucosa of the antrum will be thrown into rather symmetrical folds, which gives the pylorus a drawn-in puckered appearance. After the peristaltic wave has passed over the pylorus, and before the next wave appears, one is usually able to obtain a clear view of both the antrum and pylorus. During this period of motor activity of the stomach, that is, between the peristaltic waves, and when the antrum is open, the pylorus may be seen rhythmically opening and closing. While we cannot be sure as to the exact time when one sees the open pylorus to the best advantage, our impression is that it occurs shortly before the peristaltic wave coming down over the pre-antral zone reaches the antrum. This is probably due to the fact that when the peristaltic wave passes over the antrum, the latter for a short period of time is completely closed off from the body of the stomach. If watched carefully, the peristaltic wave can be seen first to close off the antrum completely, but as it passes downward, the antrum will be seen to open, and shortly afterward, the pylorus will be seen to close. The further one withdraws the gastroscope away from the pylorus, the less the gastroscopic image will be disturbed by peristaltic activity. In the body and cardiac end of the stomach, peristaltic activity is a negligible factor in changing the gastroscopic image. The peristaltic activity that we have endeavored to describe, is that which we believe occurs in the normal stomach. In the beginning of our gastroscopic studies with the flexible gastroscope, we selected cases in which regular routine gastrointestinal studies, including a carefully taken history, physical examination, chemical analysis, stool studies for occult blood, and complete gastrointestinal X-ray studies, failed to reveal an organic lesion in the gastrointestinal tract.

We believe that all beginners should study a large number of normal stomachs before beginning to study cases which are known or suspected of having definite pathology. Without being perfectly familiar with the appearance of the normal mucosa, one cannot appreciate or detect pathological changes when present. In some of our normal cases, we made as many as a dozen gastroscopic examinations. We made at least fifty normal gastroscopic examinations before we undertook to study cases in which a lesion of the stomach was even suspected.

We have always used the same technique. For lighting purposes, we use a battery with a volt meter, so as to have a constant amount of current at all times; otherwise, one would be likely to have enough variation in the strength of the current to produce a change in the brightness of the light, which would naturally change the appearance of the gastroscopic image. Any change in the brightness of the light would make it very difficult to read one's findings with an equal degree of accuracy.

VALUE OF GASTROSCOPY

While a gastroscopic examination is very helpful in the diagnosis of any lesion of the stomach, its greatest value is in that group of cases in which our present

routine examinations are of the least value, namely—the different types of chronic gastritis and obscure gastric hemorrhage. In the study of suspected cases of carcinoma of the stomach, we believe that early routine gastroscopy may reveal the lesion before it is possible to make a diagnosis by our usual diagnostic procedures. In our gastroscopic studies so far made, we have met with two most unusual cases. In one, an X-ray diagnosis of carcinoma of the body of the stomach had been made, but a gastroscopic examination failed to show any evidence of malignancy. This was one of our early cases, and we thought that our inability to find the lesion was due to lack of experience. This patient was operated upon and no evidence of malignancy was found. In the other, an X-ray diagnosis of malignancy of the stomach involving the prepyloric region had been made, while the gastroscopic examination showed the malignancy to be very much more extensive—cancerous nodules were found scattered throughout the body of the stomach to within a short distance of the cardia. This patient was also operated upon and nearly all of the stomach was found to be involved in the cancerous process. These two cases suggest at least, that gastroscopy is of value not only in helping to determine the presence of carcinoma, but also in determining the extent to which the stomach is involved, and whether or not anything is likely to be gained by operative treatment.

From our experience with gastroscopy, we are convinced that both X-ray studies and gastroscopic examinations should be made in all cases of suspected malignancy of the stomach. While gastroscopy with the flexible gastroscope is a comparatively new diagnostic procedure, we are quite convinced that in the diagnosis of early malignancy it will be found to be of the utmost importance. Likewise in the differential diagnosis between carcinoma and ulcer, it will be found to be of great value. In not a few cases, the decision as to whether or not the lesion under consideration is malignant or benign, will be decided by the gastroscopic examination. This statement may seem to be a little bold, but never-the-less, we believe it will prove to be true.

In the study of advanced malignancy, the diagnostic value of gastroscopy is of very much less importance. In the advanced cases, the diagnosis can readily be made by the present routine methods of examination. As previously stated, its greatest value is not in the study of malignant disease (except in the early cases where malignancy is only suspected or in the study of gastric ulcer), but in the study of the different types of chronic gastritis, and in the study of obscure gastro-intestinal hemorrhage.

CHRONIC GASTRITIS

Some of our leading gastro-enterologists believe that chronic gastritis in some form is a very definite predisposing factor in the development of carcinoma, in that carcinoma does not develop in a normal stomach, but in one already diseased. They also further believe that chronic atrophic gastritis is the one disease that is prone to be followed by gastric carcinoma. Therefore, if this etiological relationship of chronic atrophic gastritis to carcinoma of the stomach is proved to be true, it at once places this type of gastritis in the front rank, among the organic lesions of the stomach. For many years, with few exceptions, very little thought or consideration was given to the study of chronic gastritis. With the development of gastroscopy, especially with the flexible gastroscope, the condition is now known to be of quite frequent occurrence. It would therefore seem from recent gastroscopic studies, that it is probably the most frequent of gastric diseases.

Schindler classifies chronic gastritis as follows: superficial gastritis, atrophic gastritis, hypertrophic gastritis, and gastritis following operations upon the stomach. For clinical purposes, we are convinced that this classification is entirely satisfactory. The cases readily fall into these groups, and are quite easily recognized gastroscopically. In our gastroscopic studies, we have seen all grades of inflammatory changes in the mucosa, varying from the very mild grades of superficial gastritis to the very severe grades of hypertrophic gastritis. We have studied the changes in the gastric mucous membrane that occur associated with duodenal ulcer, and also those that follow operations upon the stomach.

SUPERFICIAL CHRONIC GASTRITIS

In the very mild cases of superficial chronic gastritis, the mucous membrane is somewhat redder than normal, and frequently has a slightly granular appearance. Superficial abrasions and hemorrhage into the mucosa occur rather frequently. These changes occur mostly in the antrum and pre-antral zones. It is not infrequent also, to find varying quantities of thick tenacious mucus adhering to the antral folds, or scattered throughout the pre-antral zone. We have also found small hemorrhagic areas with practically no other changes in the mucosa, in cases that did not have digestive symptoms, and where we did not expect to find any evidence of gastric disease. Just what the significance of these hemorrhagic areas is, we are not in a position at this time to state. By further observation, we hope to determine their significance, if any. Whether they have any relation to the development of peptic ulcer later on, is a question for someone to solve. The findings just described, while found mostly in the antral and pre-antral zones, may extend to a less degree upward over the body of the stomach. In this type of chronic gastritis, there is very little distortion of the mucosal folds, and practically no edema. It seems logical to state that in this form of the disease, with an appropriate diet and proper medical treatment, the symptoms should disappear and the stomach function return to normal.

CHRONIC ATROPHIC GASTRITIS

This form of chronic gastritis is characterized by atrophy of the mucosa. The mucosa loses its orange or orange red color, and assumes a grayish hue, described by Schindler as gray-green in appearance. This color change is easily recognized gastroscopically. While there is some alteration in color throughout the entire gastric mucosa, the real characteristic changes occur in localized areas, chiefly in the pre-antral zone. In these atrophied areas, one frequently sees the blood vessels very distinctly, which finding is quite characteristic of chronic atrophic gastritis. In the normal stomach, the blood vessels are seldom visible gastroscopically. The atrophic areas vary in size up to two centimeters or more in diameter. The mucosal folds are less marked on both the anterior and posterior walls, giving the stomach a somewhat smoothed-out appearance. Frequently one also sees superficial ab-

rasions and hemorrhagic areas associated with these changes. Some observers believe that superficial chronic gastritis is followed quite frequently by the atrophic form. There can be no question that some of the changes in the mucosa that are found in chronic superficial gastritis, are also found in the atrophic type of the disease. No case of complete atrophy has so far come under our observation.

CHRONIC HYPERTROPHIC GASTRITIS

In this type of gastritis, the mucosa presents an entirely different picture. The mucous membrane is very red and angry looking, abrasions and hemorrhagic areas are more frequently seen than in the atrophic form, and the amount of thick tenacious mucus is increased. The entire mucosa may be involved. These changes appear to be more marked in some areas than others, and are especially prone to occur in the pre-antral zone. The mucosal folds are swollen and broader in appearance; in some places, they seem to adhere to each other. Quite frequently the folds appear edematous and so swollen, that they are nodular in appearance. Large hemorrhagic areas are frequently noted. The whole picture is so characteristic, that one has very little difficulty in recognizing the condition.

GASTRIC HEMORRHAGE

Gastric hemorrhage is a definite indication for gastroscopy, when the usual routine examinations fail to reveal the source of the bleeding. One very important precaution however, should be taken—one must rule out a lesion of the esophagus as the cause of the bleeding. This can only be done by an esophagoscopic examination, which should always precede gastroscopy in this group of cases. Many times esophagoscopy will reveal that the bleeding is coming from the esophagus, frequently due to varicose veins. Such a finding of course, is a definite contraindication for gastroscopy. If nothing is found in the esophagus to account for the bleeding, gastroscopy may, and frequently will, locate the source of the hemorrhage.

DUODENAL ULCER

The small number of gastroscopic studies made in duodenal ulcer to date, do not permit us to draw accurate conclusions. The findings so far, however, seem to indicate that in those cases of duodenal ulcer in which the emptying time of the stomach is more or less definitely delayed, one will usually find superficial chronic gastritis in the antral and pre-antral zones. Further observations in this group of cases will be made and the results of the studies reported later.

GASTRITIS FOLLOWING OPERATIONS UPON THE STOMACH

The studies in this group have been limited to cases that had had a gastro-enterostomy performed for peptic ulcer, but had not been entirely relieved of their digestive symptoms following the operation. In all of the cases examined so far, we found a very active gastritis surrounding the stoma, spreading for some distance from the stoma and gradually fading out into normal mucosa. In a few instances, the gastritis was more extensive and involved almost the entire stomach. In not a single case did we find any evidence of marginal ulceration. Marked improvement in the gastritis occurred following the use of a bland, non-irritating diet without any other treatment. A few cases in which the digestive symptoms had been relieved following gastro-enterostomy were also studied. In this group, no evidence of gastritis was found. The entire mucosa was perfectly normal in appearance.

The Galactose Tolerance and Urobilinogen Tests in the Differential Diagnosis of Painless Jaundice*

By

FRANKLIN W. WHITE, M.D.†

BOSTON, MASSACHUSETTS

WE do not propose to go far into the large and confusing field of liver function tests, but simply to describe our results with these two well-known tests in eighty consecutive cases of jaundice in the medical wards, mostly over the age of 35, to see how much or how little they have helped in diagnosis.

By "painless jaundice" we mean cases without pain or in which pain was a mild or minor symptom. The group consists of 17 cases of acute infectious hepatitis (catarrhal jaundice), 17 cases of acute toxic hepatitis, 12 cases of obstruction of the common bile duct, and 34 chronic intrahepatic cases, mostly cirrhosis, with an acute exacerbation of jaundice. We have chosen this group of liver cases for study since here the most common mistakes are made in distinguishing "medical" from "surgical" jaundice. The mistakes are serious because prompt surgery for obstructive jaundice is the rule, while operation is needless and often dangerous when there is no obstruction outside the liver.

Liver function tests are confusing, there are so many; also disappointing because of the very large margin of safety in the liver, and the effects of regeneration of tissue. Liver function tests may be used in several ways, depending on the kind of information we want to get. First, we may try to detect the presence and amount of liver damage, second, we may use them for differential diagnosis of liver disease; third, we may follow the progress of the disease in the liver; fourth, we may use them for prognosis.

For the first purpose, the *icteric index* and *bromsulphthalein* or *rose bengal* tests are among the best, but since they are positive in practically every case of jaundice, they have little differential value. For the

*Read at the Fifth Annual Meeting of the Association of American Physicians, Atlantic City, May 5, 1927.

†From the second and fourth medical services (Harvard) Boston City Hospital.

Submitted January 31, 1927.

second purpose, the *urobilinogen* and *galactose* tests were chosen. Although we did not expect them to prove adequate routine tests of liver function, we hoped they would react differently to different types of jaundice. The tests have also the advantage of being simple and easy.

THE TESTS

These tests are so well known that they need little description. In the *Bauer galactose test* 40 grams of galactose dissolved in 500 c.c. of water and flavored with a little lemon juice is given fasting in the morning. All the urine passed in the next five hours is collected, and the amount of sugar determined. 75% of the figure found by Benedict's Solution (for glucose) equals the amount of galactose. Over three grams is considered a positive test. One function of the liver is the conversion of galactose into glycogen. The kidney has practically no threshold for galactose and if any is circulating in the blood some is excreted in the urine. The urine has been tested for galactose rather than the blood, since the latter test is far more elaborate and complex without any corresponding advantage. Galactose appears to be the best sugar for this metabolism test. It is easily absorbed, causes no gastro-intestinal disturbance, the normal tolerance is well known, and the dose is fairly independent of the size, age, or sex of the patient.

For the *urobilinogen test* we add 1 c.c. of Ehrlich's reagent (2 gr. paradimethylamidobenzaldehyde in 100 c.c. of 20% HCl) to 10 c.c. of fresh urine. If positive, a cherry red color appears in three or four minutes. The test can be made quantitative, according to Wallace and Diamond, by diluting the urine 1-10, 1-20, 1-40, 1-80, etc., until the urine just fails to show a faint red color looking through the tube from top to bottom. No antipyrine, hexamethylamine, or pyridine should be given during the test, as they may give false urobilinogen reactions with Ehrlich's reagent. If the test is positive in over one to twenty dilutions, it is considered abnormal. We have run 200 normal controls during this series of tests. To avoid variation in individual specimens of urine, a quantitative test of urobilin in the 24-hour urine could be used, but at present it is rather elaborate, and very exact methods seemed needless, as we were only concerned with gross changes.

The theory of the test is simple. There is little doubt at present that urobilinogen (and urobilin) are formed within the bowel by bacterial action whenever bile pigment is present in the bowel. Part of it is excreted in the feces and the rest is carried to the liver by the portal system. If the liver is normal, it is properly mobilized and possibly used again in the formation of new hemoglobin, and very little or none is eliminated from the blood by the kidney. A damaged liver is unable to normally convert the urobilinogen and its increased output in the urine is a sign of liver dysfunction. As far as we know there is little or no renal threshold for urobilinogen and the amount which appears in the urine is roughly proportional to the amount of damage to the liver function, but in hemolytic disease there may be a great increase in the formation of bile pigment, and thus the amount of urobilinogen in the bowel and urine is increased without indicating liver insufficiency.

We recognize the variability of both tests and other theoretical objections. Galactose in normal persons passes easily through the kidney but there may be a renal threshold in nephritis which limits its excretion. In addition to the liver a group of other organs such as the pancreas, thyroid, ovary and pituitary body are concerned in the metabolism of galactose.

Urobilinogen varies considerably in amount in different specimens of urine from the same patient, and is slowly converted to urobilin on standing so that fresh samples of urine are needed. The loss in urobilinogen is about 20% in 24 hours if the urine is placed in a cool, dark place, but in a warm, light room nearly all the urobilinogen is converted into urobilin in twenty-four hours.

We do not believe that these objections are important in this group of cases for two reasons: first, because only gross changes have value in differential diagnosis, for example: the constant absence of urobilinogen in one case compared with its constant increase in another; second, on account of the type of cases examined. We were not dealing with hemolytic jaundice in which our present diagnosis is about 100% accurate, and which strongly affects the amount of urobilinogen in the urine. We were not dealing with marked nephritis which would interfere with the excretion of sugar or pigments. We were not dealing with definite endocrine disturbances such as thyroid, pituitary, or adrenal disease which would influence the sugar metabolism. No diabetics were met in this series.

We soon learned the variation in urobilinogen which occurs from day to day, from morning to afternoon, and at different stages in an attack of jaundice, and learned *the necessity for a course of six or eight urobilinogen tests*, beginning early in the attack, if possible, or at the height of the jaundice and extending over ten days to two weeks, which is very easy to do since the test is so simple. A course of tests is usually far more valuable than any single test which has limited value and may even be misleading. In a doubtful case of obstruction of the common duct we can usually well afford to wait a week or two and run a series of tests to try to rule out intrahepatic jaundice.

On account of the dissociation of functions in the liver, it seemed logical to use two kinds of tests in addition to the icteric index in order that one test might back up the other. For example: the urobilinogen test is quite constantly positive in all kinds of liver disease *except* where no bile reaches the bowel. The galactose test, on the other hand, is less sensitive, but is independent of the presence of bile in the bowel. While the tests do not accurately measure liver function they may be used to differentiate one pathologic process in the liver from another.

RESULTS

The cases are grouped as acute infectious, and toxic hepatitis; obstructive jaundice, and chronic intrahepatic jaundice, mostly cirrhosis. The basis for the classification of cases has been the clinical history and examination, with special effort to discover a possible cholecystitis in the cases classed as infectious hepatitis; by operation or autopsy in the cases of obstructive jaundice; and by the clinical course in the cases of chronic intra-hepatic jaundice, supplemented by some biopsies and autopsies. The tables show the age of the patient, the duration of the jaundice, the maximum jaundice as measured by the icteric index, the galactose excretion in grams, and the urobilinogen in urine. The latter figures represent the greatest degree of dilution which gave a positive test, e.g. 40 means present in 1-40 dilution, etc.

Infectious Hepatitis (Catarrhal Jaundice). In seventeen cases, fourteen gave a positive urobilinogen test at some period of the disease and ten cases a positive galactose test. In looking over the group it was found that of the seven negative galactose cases, three were

very mild cases (Cases 1, 2 and 3) and in one (Case 4) the tests were first made in the late convalescent stage of the jaundice. So, it seems desirable to divide these cases into two groups. A mild or convalescent group with the duration of the jaundice only two or three days and with an icteric index of 10-40, and a well-marked group with the duration of the jaundice from one week to one month and an icteric index of 25 to 250.

In the five cases of the mild or convalescent group the galactose test was normal in all and the urobilinogen was positive in four. In this mild group the tests were not particularly needed for diagnosis and the galactose test gave no help. In several of these mild cases (Nos. 1, 3, 4 and 5) where the carbohydrate function showed no change and the galactose test was within normal limits, the positive urobilinogen test had definite value in indicating the true nature of the

disease. In the remaining well-marked group of 12 cases the galactose test was positive in ten and the urobilinogen positive in ten. In two cases (Nos. 10 and 13) both tests were normal; they will be discussed below.

The course of the tests was interesting, showing the variation early and late in the jaundice, with different degrees of liver damage and recovery. When we had an opportunity to follow a well-marked case of infectious hepatitis from the start, the urobilinogen at first was moderately increased, then followed a period of a few days to a week when little or no bile reached the bowel, and we had the typical "clay stools," and the urobilinogen was negative. If the middle-aged patient is first examined at this period, the suspicion is raised of obstructive jaundice caused by cancer, a silent gall stone, or stricture of the common duct (more than half our infectious cases were between 40 and 60 years of age). It is here that the galactose test occasionally proved useful. It was usually positive at this time, indicating acute diffuse liver cell damage, and this was backed up by the clinical course, the return of bile to the stools, the high urobilinogen later, and the gradual disappearance of the jaundice.

In none of the 34 cases of infectious and toxic jaundice were the urobilinogen tests negative for more than one or two weeks (and usually only for a few days) at the period when no bile reached the bowel, and about three-quarters of the toxic and infectious cases reached the hospital when the "clay stool" period was passing or had passed and our urobilinogen tests were high from the start. In one case, a hospital officer, aged 28, with vague digestive symptoms for two weeks, nothing important was found on the first examination except a strongly positive urobilinogen test (in 1 60 dilution), which precede the appearance of jaundice by several days, and suggested the early diagnosis.

When we consider the four cases which did not follow the general rule, it is evident that the time of the test in relation to the period of the disease is very important. In Cases 4 and 5, the galactose tests were done only in the convalescent period and were both normal. In Case 10, the galactose test was first done and found normal just as the patient was beginning to rapidly recover; the icteric index dropped from 150 to 50 in the following week. This is also one of the rare cases where the urobilinogen remained within normal limits (the readings were: 8-16-0-2) in spite of intense acute jaundice.

In Case 13 we had real difficulty in diagnosis and the two tests gave no help. This was a sixty-year old man with two weeks of steadily increasing, deep, painless jaundice; the icteric index increased from 100 to 200. He had normal galactose tests and five urobilinogen tests showing complete absence over ten days; the diagnosis wavered between a sub-acute diffuse hepatitis with a long period of acholic stools and an obstruction of the common duct, and the patient was finally sent to the surgeon. A longer period of observation and tests might have avoided this mistake. The patient died of broncho-pneumonia a week later. At autopsy there was no obstruction of the bile passages but a late stage of moderate focal hepatitis with some regeneration of lobular cells. The bile capillaries were somewhat dilated. There was no cholangitis. The diagnosis was healing infectious hepatitis.

It is interesting to note that in the differential diagnosis between acute infectious hepatitis and obstructive jaundice the error has been only in one direction. One case of acute infectious hepatitis was wrongly called obstructive jaundice, no case of obstructive jaundice has been called infectious hepatitis.

The tests have definite value in prognosis. In the convalescence from acute infectious and toxic hepatitis the simple urobilinogen test has been especially useful in measuring the speed and degree of recovery of normal liver function. The milder cases clear up promptly, the more severe type with possible development of subacute yellow atrophy or cirrhosis show high residual urobilinogen tests long after the immediate symptoms have subsided.

Toxic Hepatitis. Of the seventeen cases, fourteen followed the use of arsphenamin, two of cincophen, and one of gold thiosulphate. All were well marked with jaundice lasting one week to one month, and a maximum icteric index of 45 to 160. In all cases the urobilinogen was increased, and was present in dilutions of 1/40-1/130. In all but two cases the galactose test was positive. In general the two tests were closely alike in the infectious and toxic groups, as might be expected. They were less important in diagnosis in toxic hepatitis when the history of the drug was obtained. See Illustrative Cases, No. 3.

The two cases of hepatitis in which the galactose test was not definitely positive followed arsphenamin. One (No. 4) was "suspicious" with 2.4 grams of galactose in the urine after the test and with urobilinogen of 40, and one (No. 9) showed no galactose in the urine after two tests, while the urobilinogen was present in 1/130 dilution. In these two cases with normal galactose tolerance, the strong urobilinogen tests were an aid in diagnosis of the condition of the liver.

Obstructive Jaundice. In our twelve cases are ten of cancer of the head of the pancreas, or common duct, and two benign cases, namely one large impacted stone in the common duct and one tight stricture of the common duct, the diagnosis was confirmed by operation in eight cases and post mortem in three. The ages were 43-69, the duration of the jaundice ten days to four months, and the maximum icteric index per case was 65-200. The stools in nine of the cases were gray or clay colored throughout, in two, light yellow at first and clay colored later. In the stone case they were variable. The liver was enlarged in nearly all of the cases, and the gall bladder was palpable in three. The spleen was not palpable in any case.

In the eleven cases of cancer and stricture, urobilinogen was almost entirely absent as a result of very little or no bile reaching the bowel. Four to eight tests were made in each of the eleven cases over a period of about two weeks with 69 negative and only one slightly positive test. The *absence* of urobilinogen in every case but one of marked obstructive jaundice (and the almost complete absence in every test) was a strong contrast to its *presence* in every case but one of infectious and toxic hepatitis at some time in the course of the jaundice, almost invariably in much increased amounts. The continued absence of urobilinogen was a valuable sign of marked obstruction of the common bile duct and since we have no really good test for bile in the feces, the urobilinogen test in the urine takes its place up to a certain point and is cer-

talnly much more definite than the often vague descriptions of the color of the feces. In our one case of silent stone in the common duct the galactose test was normal and the urobilinogen variable but always increased (40-80). It stands out in sharp contrast to the persistently negative tests in the other cases of obstruction.

In the "painless jaundice" group cancer involving test and a cholecystenterostomy was done. An autopsy showed a small cancerous stricture of the common duct 3 cm. above the papilla. The liver weighed 1570 grams. There was marked dilation of the hepatic duct. Microscopic examination showed stasis in the bile capillaries and a very moderate degree of damage of the lobular cells. She was one of our most severe and long-standing cases of jaundice, and the low galactose tolerance

*In Case 5, five urobilinogen tests were negative. One to 1 gave a faint positive test to undiluted urine.

the common duct predominates (ten of the twelve cases) and has produced an obstruction of a very complete type. Persistent acholia of the stools appears to be the rule in malignant obstruction of the common duct, and rarely occurs in other forms of jaundice. It often appears in hepatic degeneration but rarely lasts more than a week or so, often only a few days. The obstruction due to stone is rarely complete (see Case 10). This is clearly shown by these simple tests for urobilinogen and corresponds with the results obtained by C. J. Watson using a much more complete quantitative method of analysis of the 24-hour urine and feces.

A green color in the urobilinogen tests was found in four of the ten cases of cancerous obstruction and never in any other kind of case and it seemed possible that it might have special diagnostic value, but the literature shows otherwise. Simici and Popescu thought it was due to a precursor of urobilinogen. Umber and Bansi found it in severe toxic jaundice with transition into an acute yellow atrophy, and Jendrassik and Swartz finally showed that it has nothing to do with urobilinogen and has no relation to the severity of liver damage, but is due simply to the simultaneous presence of bilirubin and nitrites in the urine in sufficient concentration.

The galactose tests were normal in ten cases, suspicious in one (2.25 grams) and moderately positive in one (3.52 grams). The exceptional case was examined carefully for some explanation. She was a woman of 66 with cancer of the common bile duct. She had jaundice of over two months duration, gray stools with a complete absence of urobilinogen on six tests and a positive galactose test (3.52 grams). She was diagnosed as obstructive jaundice due to cancer, or common duct stone, regardless of the positive galactose may perhaps be due to more marked functional damage to the liver cells than was present in the other cases (even in the absence of marked histologic changes in these cells).

Chronic Hepatitis. Another group of middle aged patients, who may have an essentially painless jaundice, needs to be separated from the external obstructive or surgical group if possible. The tests were also used in this group to see if they would give additional diagnostic help.

The group of 34 patients included 23 cases of alcoholic portal cirrhosis, 1 hemachromatosis, 1 chronic toxic cirrhosis (CCl_4), 2 biliary cirrhosis (infectious), 1 Banti's disease, 1 syphilis of the liver and 5 chronic hepatitis associated with a pathological gall bladder without definite obstruction of the larger bile passages. The diagnoses were based on 6 operations, 5 for pathological gall bladder, 1 in a case of cirrhosis, 2 autopsies, and on clinical findings in 26 cases. These cases have been very thoroughly studied over periods of several weeks to several years. The liver was enlarged in nearly all and markedly so in about 2/3, the spleen was palpable in about 1/3, ascites was present in about 1/2, the Wassermann or Kahn was positive in about 1/4. The stools were brown in all cases at some period of the jaundice, but were clay colored part of the time in 6 cases.

In this group the tests are much less constant and definite than in the other two groups, probably as a result of the various combinations of liver cell atrophy and regeneration found in the chronic liver cirrhoses. Urobilinogen was almost invariably present and was increased in 27 cases (77%), being present in dilutions of from 1:30 to 1:500, which was interpreted as a sign of varying degrees of liver damage. In nine cases

(25%) both galactose and urobilinogen were positive. Acute infection or toxemia (alcohol, drugs, etc.) may complicate chronic liver damage in cases of cirrhosis and the urobilinogen and galactose tests become strongly positive during the jaundice, clearing up later and becoming normal, or nearly so, when the jaundice is gone. In eight cases both tests were normal.

Thus we see that almost all the cases differed from serious progressive grades of obstructive jaundice such as is found in cancer or stricture involving the common duct, by showing the continued presence of normal or increased urobilinogen. In some cases the results closely resembled those obtained in acute infectious or toxic hepatitis. In comparing the urobilinogen tests with normal persons, eight of the group were within normal limits, (0-20), four showed a slight increase (30), and the other twenty-three a decided increase (40-500). The galactose test was normal in 3/4 of the cases.

The addition of the Takata test in some of our later cases (by Dr. C. W. Heath and Dr. F. S. King) has made the diagnosis of cirrhosis of the liver much more definite. This test was used in 16 cases in this chronic group and was positive in 13. So, the laboratory finding in our cases of cirrhosis, with well-marked jaundice, are, urobilinogen usually increased (77%), galactose tolerance usually normal (75%), and Takata usually positive in well-marked cases (81%). Heath and King have already reported the results of the Takata tests.

Although there was much variation in the results

g.b.—gastrointestinal tract biopsy, op.—operation, P.M.—post mortem examination.

of the tests in this chronic group, there was usually no difficulty in diagnosis from the surgical obstructive cases of jaundice due to cancer or stricture of the common duct because of the *continued presence* of normal or increased urobilinogen and the occasional positive galactose tests in combination with some of the other clinical features of cirrhosis such as a history of alcohol, enlargment of the liver and spleen, dilated veins in the abdomen and esophagus, ascites, hemorrhage, Takata test, etc.

Only one case (No. 32) of cirrhosis was explored on account of some doubt in the minds of some of the visiting physicians and surgeons about the possibility of partial obstruction, external to the liver. Case 32 was a man of 72 with a history of lues and moderate long-continued use of alcohol. He had one course of bismuth injections five months ago. For one month there was symptomless jaundice becoming rather deep. The icteric index in the last 2½ weeks was 50-75-75-75-100-100. A firm liver was felt 5½ cm. below the costal margin. The spleen was not palpable. There was no ascites. The stools varied from light yellow to gray. There was mild anemia. A barium meal showed a small diaphragmatic hernia of the stomach. A flat plate of the gall bladder region was negative. The urobilinogen tests were 16-64-16-32-4-8. The galactose test showed no sugar excretion. A duodenal drainage showed nothing abnormal. Two Takata tests were negative. Our diagnosis was intrahepatic jaundice due to a chronic hepatitis. This was based on the alcoholic history, firm large liver, and the presence of bile in the stools, and the *constant* presence of urobilinogen in normal and increased amounts. The galactose test gave little help. Operation was considered somewhat risky on account of the probable presence of a chronic hepatitis, but was done to rule out a possible partial obstruction outside the liver which might give a similar picture. At operation a large, firm, slate-colored liver was found with an atonic gall bladder and no stones. A biopsy of the liver showed typical alcoholic cirrhosis. The patient made a normal recovery from the operation.

There were only six cases of gall bladder disease in our "painless jaundice" group in the medical wards. One is listed in the obstructive group, Case 10, a large gall stone in the common duct causing partial obstruction; five are listed under chronic intrahepatic jaundice, Cases 16, 22, 23, 27 and 28, all of which at operation showed gross chronic changes in the gall bladder and liver, also three biopsies showed a definite hepatitis. In five the urobilinogen was markedly increased and in one was normal. The galactose tolerance was normal in all. The one silent common duct stone with increased urobilinogen stands out in sharp contrast to the ten cases of malignant obstruction of the common duct and one stricture, all of which had persistently absent urobilinogen. The two tests gave no help in distinguishing the five cases of hepatitis associated with a pathological gall bladder from the other cases of chronic hepatitis. The two cases listed as biliary cirrhosis, Cases 9 and 15, were considered due to infection with B. Coli. There was no evidence of any obstruction outside the liver.

SUMMARY

TABLE IV

Well marked painless jaundice—80 cases

	Number of Cases	Icteric Index	% Positive Galact.	Urobilinogen % Present	Urobilinogen % Increased	Takata
I Acute Toxic Hepatitis	17	50-180	88	100	100	Not done
Acute Infectious Hepatitis	17	40-250	60*	94	88	Not done
II Obstructive	12	65-200	8	8	8	Not done
III Chronic Intrahepatic (Cirrhoses, etc.)	34	30-225	25	97	77	81**
Total	80					

*If five cases are omitted., three very mild and two in which the tests were made only in the convalescent period, the per cent of positive galactose tests is 83 instead of 60.
**81% of 16 cases tested.

DISCUSSION OF RESULTS

Liver function tests are disappointing at times because a damaged liver, especially a chronic one, may have normal functions of several kinds. We have simplified the problem considerably by not using a large group of function tests indiscriminately in all kinds of liver disease, to detect the presence and amount of liver damage, but in applying these two simple tests to distinguish, if possible, the different types of painless jaundice, especially the medical from the surgical.

It is obvious that the clinical grouping of cases of jaundice as intra hepatic or obstructive is somewhat arbitrary. While diffuse liver cell damage is the characteristic finding in acute infectious hepatitis (catarrhal jaundice) there are some which show obstruction of biliary capillaries by bile thrombi or cholangitis in the early stages, and, conversely, there is some liver cell damage in all prolonged biliary obstruction outside the liver, and in the cirrhoses we have a combination of varying degrees of atrophy and regeneration. The tests are most useful where one type of pathology predominates, as it so often does, and we make the diagnosis of this predominant factor.

The results of the tests are shown on Tables I, II, III and IV. In well-marked infectious and toxic hepatitis during the height of the disease the urobilinogen was nearly always present (94 to 100%), and nearly always increased (88 to 100%). The galactose was positive as a rule (83 to 88%).

In marked obstructive jaundice, due to cancer or stricture or impacted stone in the common duct, the

urobilinogen was nearly always absent (92%); the galactose was nearly always normal (92%).

In chronic intrahepatic jaundice (mostly cirrhoses) the urobilinogen was nearly always present (97%) and increased as a rule (77%). The galactose test was positive in 25% of the cases. In sixteen of the cases of cirrhosis in this group, the Takata test was done by Drs. Heath and King. Thirteen were positive (81%) and three negative. The six gall bladder cases, all with associated hepatitis, could not be clearly distinguished by the tests from other types of chronic hepatitis. The urobilinogen was increased in five, normal in one. The galactose was normal in all.

Our results in well-marked cases of painless jaundice agree in general with those of Bauer and most other recent authors such as Woerner, Wallace and Diamond, Jolliffe, Piersol and Tumen, Shay and Schloss, Davies, Rosenberg, Schiff and Senior. The tests were positive as a rule where acute, diffuse cell damage predominates, as in catarrhal jaundice and toxic hepatitis. A positive galactose test (with diabetes ruled out) means liver degeneration and the excretion of large amounts, 6-7 grams, is practically conclusive. The tests were negative as a rule where there was gross mechanical obstruction of the common duct. In the cirrhoses we disagree with Bauer who says that "*almost all cirrhoses show a strongly positive galactose test.*" In our cases only one-fourth were positive.

Banks, Sprague and Snell found more positive galactose tests in the obstructive group than we did and explain this by the presence in their series of many severe cases of long duration with advanced destruction of the liver parenchyma, so that the liver reserve had been overcome and regeneration had failed.

Table IV gives a summary of both tests in the three groups of cases. In comparing the cases of group 1, acute diffuse liver cell damage, with the cases of group 2, subacute obstruction outside the liver due to cancer or stricture of the common duct, both tests were very different as a rule. The galactose being almost always positive, and the urobilinogen almost invariably present in increased amounts in group 1, and the galactose being almost always normal and the urobilinogen almost invariably absent in group 2.

In comparing group 2, the obstructive cases, with group 3, the cirrhoses, the galactose test gave little help. The urobilinogen test was very different as a rule, being almost invariably absent in group 2 and practically always present in group 3, and in increased amounts in over 3/4 of the cases.

The important feature is the separation of medical *from surgical cases of painless jaundice.* We have avoided sending several middle-aged cases of subacute hepatitis to the surgeon for exploration. We certainly hesitate to advise exploration in such patients if both galactose and urobilinogen tests are strongly positive and the stools are brown.

We have also been able to urge the surgeon to operate on several obstructive cases which he believed were chronic hepatitis. We have definitely improved our differential diagnosis of medical from surgical jaundice, and of fifteen cases sent to the surgeon, only one went with a wrong diagnosis. The onset of catarrhal jaundice was discovered once by the urobilinogen test before the jaundice appeared.

All liver function tests are affected much more by diffuse changes of the whole liver even though slight, than by complete destruction of quite large portions of the liver if the remainder is normal (tumors, etc., not involving bile ducts). As in the kidney, there may be resting units which can be used in an emergency. Thus, we may expect changes in liver function only when practically all the liver cells are acutely damaged, or when chronic liver disease has gone so far that few or no normal cells are left and regeneration has failed.

Vigorous regeneration of liver cells in the convalescence from acute disease and in the remissions of chronic disease give us normal metabolic tests. In obstructive (and hemolytic) jaundice enough normal liver tissue is left, in the earlier stages at least, to carry on carbohydrate metabolism and the galactose test is usually normal.

It is not wise to base diagnosis on single tests which may be misleading on account of constant changes in liver function during an acute or subacute illness. For example: urobilinogen is usually absent in the acholic stool period of acute infectious and toxic hepatitis, although usually strongly positive at other times. The test is also usually normal in the late convalescent period of mild acute hepatitis and in chronic hepatitis in a period of compensation. The urobilinogen test may be positive or normal in the early stage of malignant obstruction of the common duct, although persistently negative later. *A course of tests* on the other hand will usually give the whole picture, and avoid mistakes.

We found the urobilinogen test useful, simple and inexpensive. A series of tests could easily be run every day or two for one or two weeks. It proved the more sensitive test of the two. For example: in five of our cases of acute infectious and toxic hepatitis (including most of the mild ones) the urobilinogen test was positive while the galactose test was normal. The same was true in 18 cases of chronic cirrhosis of the liver. It appears to be a very delicate test of liver dysfunction but is, however, low or absent in cases where very little or no bile reaches the bowel such as obstructive jaundice or for a short period (a week or less) in the early stages of acute infectious or toxic hepatitis. It is probably more often useful than the galactose test in differentiating intrahepatic from external obstructive jaundice, and occasionally some factor such as dehydration, oliguria or inability to take the dose on account of vomiting may make the galactose difficult to use or to interpret, but the combined use of the tests is on the whole best of all.

There was a minor difficulty in interpreting the tests in a few cases. The more definite the test the better; for example, if the galactose excretion is 1 gram in one case and 6 grams in another we have no hesitation in pronouncing one normal and one abnormal. But, if the excretion is between 2.5 and 3 grams the interpretation of the result is not easy, and the test should be repeated. We found few such borderline cases, and, of course, we had the urobilinogen test as an additional help. A large amount of galactose, 5 or 6 grams or more, is clear evidence of liver cell injury though normal galactose does not exclude it.

There was evidence of dissociation of liver functions. There was no definite relation between the degree of jaundice and the degree of galactose tolerance. When an acute or subacute disturbance is clearing up the galactose tolerance usually reaches normal before the icteric index. Althausen has suggested that this high index with normal liver function may be due to bilirubin which has been stored in the tissues, and is

being carried by the blood to the liver for excretion. Occasionally, the icteric index may be low while poor galactose tolerance persists.

The tests have some value in prognosis not only by showing the extent of the dysfunction, but also by following the course of the illness and showing whether the liver damage persists or is increasing or lessening. The urobilinogen test may remain positive after all other signs are gone in acute toxic or infectious hepatitis, showing some residual liver damage.

The urobilinogen test is a guide to the diffuse liver injury which may occur in an attack of cholecystitis. The urobilinogen may increase to 40 or 50 during the attack, and then drop to normal within a week after the attack is gone. Watson has shown the same effect on the urobilin excretion in attacks of cholangitis associated with a ball value stone in the common duct.

In gall bladder cases, with or without partial obstruction of the common duct, the tests were not distinctive. Some were normal, some were abnormal, depending, apparently, on the amount of associated hepatitis or infection. The tests gave little help in distinguishing this type of case, which is often surgical, from the medical cases of acute and chronic hepatitis. Fortunately, silent stones in the common duct are rather uncommon and we may expect to get evidence in most gall bladder cases in other ways—by the history and ordinary physical examination, by the X-ray and the duodenal tube.

A study of the exceptional results was profitable. They may be due to the variability of the tests, the period of the disease, or its character (the simultaneous presence of obstruction and liver cell damage). The diagnosis is best made not by early impressions and early tests, but usually, in a difficult case, from the clinical course over a period of intensive study of a week or two.

The time of the test in relation to the period of the disease is very important. Mild and convalescent cases are apt to have normal tests; fortunately, they are less important in diagnosis. The amount of functioning tissue in the liver is constantly changing and tests should be made at the height of the jaundice or just before this to have their full value. In an exceptional case of intense acute hepatitis with deep jaundice, both tests may remain normal during the period of observation of 10 days to 2 weeks; the urobilinogen perhaps because very little or no bile reaches the bowel, and the galactose for some reason which we cannot altogether explain, perhaps the remarkable functional reserve of the liver.

Our cases of marked obstructive jaundice, due to cancer or stricture involving the common duct, have reacted to the tests in a definite and uniform manner with only one exception. Some positive galactose reactions seem inherent in the nature of the test and were probably due to the presence of serious functional liver cell damage in this case of severe and long standing obstruction. The per cent of positive galactose tests in this group (9% in our series) will depend considerably on the number of this type of case which is included in it. Perhaps a longer experience may show a greater per cent, as has been reported by Snell; however, the constant absence of urobilinogen, especially in the case of malignant obstruction, has given valuable help in making the correct diagnosis.

In cancer involving the common duct the interval between the onset of jaundice and complete obstruction of the duct is short, usually only 2 or 3 weeks because the first appearance of jaundice means decided narrowing of the duct. In cancer this complete obstruction is due to rapid constriction and closure of the common duct, while in stone there is no constriction, the duct dilates above the stone and some bile goes by.

Two rare exceptions to this rule have been seen since first writing this paper. One patient (B.B.) aged 76, had a small soft pedunculated adeno-carcinoma in the common duct causing only partial obstruction with cholangitis and multiple abscesses in the liver. Urobilinogen was always present in the urine and usually high. Conversely, one patient (J.J.) aged 52, had gall bladder disease and the hepatic and common ducts were solidly plugged with putty like material and gravel, causing complete obstruction and entire absence of urobilinogen in the urine in 5 tests.

Partial obstruction external to the liver due to common duct stone, especially when complicated with infection and hepatitis, may be difficult or impossible to distinguish by these tests from the jaundice due to pure chronic diffuse disease of the liver such as the cirrhoses. The urobilinogen and galactose tests may be normal or increased in both and the diagnosis must be based on other clinical data. Thus some gall bladder cases, which are often surgical, may not be distinguished by these tests from the medical cases of acute and chronic hepatitis. This difficulty occurred only once in our series, in case 10, group 2, a large gall stone in the common duct. The correct diagnosis was made from other clinical data. One case of cirrhosis, case 32, group 3, was explored because the possibility of partial external obstruction was seriously considered.

Improvement in the diagnosis of these cases of jaundice may be due in part to greater interest and more intense clinical study as well as to the use of special tests, but we believe the latter have real importance. The better the clinician, the better he will be able to interpret the tests and to combine them with the rest of the clinical picture.

SUMMARY

The urobilinogen and galactose tolerance tests in the urine were used in 80 cases of painless jaundice in the medical wards. Of seventeen cases of acute infectious hepatitis, urobilinogen was present in sixteen and increased in fourteen. Ten gave a positive galactose test. The negative results occurred largely in the very mild cases or in those tested only in the convalescent period. In twelve well-marked cases tested during the height of the jaundice, the galactose was positive in ten and the urobilinogen increased in ten. In seventeen cases of acute toxic hepatitis, the urobilinogen was increased in all and the galactose positive in fifteen. In twelve cases of jaundice due to obstruction outside the liver, urobilinogen was absent in eleven and increased in one, the galactose normal in ten and positive in one.

In thirty-four cases of chronic hepatitis, mostly cirrhoses, urobilinogen was present in thirty-three and increased in twenty-seven. The galactose test was positive in nine. Both tests were normal in eight cases. In sixteen well-marked cases of cirrhosis the Takata

test was positive in thirteen. In six gall bladder cases, all with associated hepatitis, the urobilinogen was increased in five and normal in one. The galactose was *normal in all.*

The tests were positive as a rule where diffuse liver cell damage predominates as in catarrhal jaundice and toxic hepatitis. A positive galactose test in painless jaundice (with diabetes ruled out) means liver degeneration, and the excretion of large amounts, 6-7 grams, is practically conclusive. The tests were negative as a rule where there was malignant obstruction of the common bile duct. In painless jaundice the important diagnosis is between the medical and surgical type. This is especially true in middle life when cancer is *frequent.* The combination of these two simple tests in the urine for urobilinogen and the galactose tolerance has proved a useful aid in distinguishing several groups of medical and surgical cases; namely, acute and chronic, toxic and infectious hepatitis from painless obstruction outside the liver.

One of the most important findings was the persistent absence of urobilinogen in obstructive jaundice *due to cancer of the head of the pancreas* or common bile duct. Persistent acholia of the stools developing rather early, after two or three weeks of jaundice, with *persistent absence of urobilinogen* in the urine, appears to be the rule in malignant obstruction and rarely occurs in other forms of jaundice. In acute hepatitis it is only temporary, and in the obstruction due to stone is rarely complete. In our one case of silent stone in the common duct the *constantly increased* urobilinogen was in sharp contrast to its *persistent absence* in the ten cases of malignant obstruction

In gall bladder cases, in general, which are often surgical, the tests were not distinctive. They depended, *apparently, on the amount of associated hepatitis* or infection and resembled those in the medical cases of acute and chronic hepatitis, and the diagnosis was made from other clinical data. Occasionally there may be great difficulty in distinguishing painless *partial* obstruction of the common bile duct with secondary damage to the liver from a primary subacute or chronic diffuse disease of the liver. This occurred once in our series

On account of the variation in liver function at different periods of an attack of jaundice and some variation in the tests themselves, it is not wise to base diagnosis on a single test. A course of tests, beginning early if possible and carried through the height of the jaundice for a week or two, is far more valuable.

A positive galactose test in painless jaundice indicates liver degeneration, a normal test does not always exclude liver cell injury. The urobilinogen test has value in showing the presence or absence of bile in the bowel, as well as being a very sensitive indicator of *liver disturbance. It is a more definite guide to liver* dysfunction than the galactose test (if hemolytic jaundice is excluded) and is more often useful in distinguishing intrahepatic from external obstructive jaundice, but a combination of the two tests is best of all.

The tests have a definite value in prognosis by measuring the speed and degree of recovery of liver function after an attack of jaundice. The urobilinogen and galactose may remain positive long after active symptoms have disappeared showing residual liver damage. In an occasional borderline case the tests may be inconclusive, or even misleading.

Finally, these simple tests have proved useful aids and have definitely improved our differential diagnosis of painless jaundice, and deserve to be used more in this particular field.

CASE REPORTS

The following case reports illustrate the application of the tests in diagnosis; only relevant data are given: The first case shows how one test backs up the other and the value of the galactose test at a time when no bile was reaching the bowel.

1. (*Case 5—Infectious Hepatitis*). *J. D. A.*, a man of 45, had for ten days a gradually increasing symptomless jaundice with loss of 8 pounds in weight. Physical examination showed nothing important. The icteric index was 200 on admission and rose to 250. The stools remained clay colored during the first week of observation. The white blood cells were 6300. There was slight anemia. Roentgen rays of the stomach and bowel after a barium meal, also a flat plate of the gall bladder region, showed *nothing* abnormal. Four urobilinogen tests in the first week were negative. The first impression was obstructive jaundice due to cancer of the head of the pancreas or a possible silent stone in the common duct. The galactose test, however, showed 6.8 Gm. output and surgical treatment was put off and the diagnosis of infectious hepatitis (catarrhal jaundice) was suggested. This was confirmed by the subsequent course. At the end of a week the stool began to show some brown color and the jaundice to lessen, the index dropped from 250 to 50 in the next 11 days. The urobilinogen rose to 45 and gradually dropped to *normal* at the end of four weeks from admission. At the end of 2½ weeks the galactose test had become normal showing no excretion of sugar. Recovery was uneventful.

The second case illustrates the course of the tests in a *fairly typical case of well-marked infectious hepatitis* (catarrhal jaundice).

2. (Case 7—Infectious Hepatitis). *E. J.*, a rather plump woman of 40 years, with three children, complained of malaise for one week followed by jaundice for one week. There was some nausea and gas with rare vomiting and a dull ache in the right side of the abdomen. The edge of the liver was just felt. The spleen was not palpable. X-rays of the gastro-intestinal tract and gall bladder *region were negative.* The stools were pale yellow with a *positive* Benzidin test for blood. At entrance the icteric index was 75, the urobilinogen 80 and the galactose excretion 4.8 Gm. The icteric index rose to 140 and then gradually dropped to 10 at the end of three weeks. The urobilinogen readings were 80, 90, 80, 60, 30, 10 in the *same* period. At the end of three weeks the galactose excretion was 2.7 Gm. The patient made a gradual but uneventful recovery. A Graham test of the gall bladder after the *jaundice* was gone gave a normal result.

The third case is a good example of a severe *toxic* hepatitis masquerading as obstructive jaundice.

3. (Case 10—Toxic Hepatitis). *T. S.* This 72 year old woman was admitted with a story of 10 days' jaundice. She was very ill and the history incomplete, *recent* dyspnea and edema of the feet, and for several weeks anorexia, regurgitation of food and some vague epigastric distress. The *icteric* index was 200; she had an arteriosclerotic heart, the liver was not palpable, there was tenderness in the epigastrium, and a question of a mass in the gall bladder region. The temperature was normal to 99.8°. The white blood count 11000 to 9000; the stools gray with a tinge of brown. Our first impression was an obstructive jaundice, but several urobilinogen tests were 40 and the galactose excretion 3.6 Gm. Both tests pointed toward intrahepatic rather than obstructive jaundice. Finally a *history* was obtained from the family of recent joint pain

and the use of cincophen tablets two or three times a day for a month. The diagnosis of toxic hepatitis was then definitely established. The stools became brown and the urobilinogen remained above normal. The patient became comatose and in spite of the liberal use of glucose intravenously and by Murphy drip died ten days after admission. The liver weighed 970 Gm. with marked toxic central necrosis and small scattered areas of regeneration. *Diagnosis*, subacute yellow atrophy of the liver.

Number four illustrates the use of the tests in a case called "catarrhal jaundice" by the surgeon.

4. (Case 1—Obstructive Jaundice). *A. D.*, was a man of 55 with a story of former rather excessive use of alcohol. He had jaundice for 2½ weeks with mild abdominal cramps and three loose stools at the onset, none since. Some epigastric fullness and "gas." Loss of 10 pounds in the last two years. Physical examination showed nothing important except arteriosclerosis and hypertension. Icteric index, 100. Stool, light yellow, later gray. Benzidin test for blood, moderately to strongly positive. Temperature, normal. Red blood cells, 4,030,000. White, 4250. Hemoglobin, 75%. Barium meal and enema showed nothing abnormal. Urobilinogen, 0. Galactose, 0.51 Gm. The tests favored the diagnosis of obstructive jaundice. The surgeon who saw him suggested "catarrhal jaundice" and advised further observation. The stools continued clay colored. The urobilinogen tests were entirely negative for another week and a second galactose test was normal. Exploration was urged with the diagnosis of obstructive jaundice due probably to cancer of the head of the pancreas. At operation this was found.

Number five illustrates the use of the tests in the differential diagnosis between portal cirrhosis and obstructive jaundice.

5. (Case 4—Obstructive Jaundice). *S. D. P.*, age 59. This man had drunk a bottle of wine daily for many years, was usually well, but had jaundice for three weeks with loss of 7 pounds of weight, and a dull ache in right upper quadrant extending to the back. Stools and urine were "yellow." Abdominal examination showed a firm, smooth liver one or two fingers breadth below the right costal margin with a smooth projection on the right side which was considered a Riedel's Lobe or possibly a distended gall bladder. The icteric index was 75. The stools, light yellow. The temperature normal. The urobilinogen, 0. The galactose excretion, 0.8 Gm. The surgeon made the diagnosis of alcoholic portal cirrhosis and suggested further observation. Five urobilinogen tests were entirely negative, (one showed a green color), and the stools became clay colored and remained so. We felt that the tests strongly favored obstructive jaundice, particularly the uniform absence of urobilinogen in the urine, and urged exploration. A cancer of the head of the pancreas was found.

Production of Peptic Ulcers in Rats and Mice by Diets Deficient in Protein*

By

FREDERICK HOELZEL

and

ESTHER DA COSTA, M.S.

CHICAGO, ILLINOIS

ULCERATION OF THE PROSTOMACH

BUCHNER, Siebert and Molloy (1) found that *ulceration* of the prostomach occurred in some rats that were starved every other day during a period of 17 days. More striking ulceration was produced when rats subjected to such a regimen were given histamine on starvation days. Bürkle-de la Camp (2) confirmed the findings of Büchner, Siebert and Molloy with intermittent starvation plus histamine but he did not observe ulcers in rats that were starved during single periods of five days or less. The possibility of ulceration following starvation was of particular interest to one of us (F. H.) because of personal experiences which included fasting every other day for five consecutive months and single fasts of as long as 41 days. Moreover, the 41-day fast and a 33-day fast were undertaken as part of studies of the effect of variations in the protein intake on the fasting gastric acidity (3b) and hunger sensation (4). In these studies, it was found that the fasting gastric acidity was increased by protein restriction and after fasting and that a peculiar and intense hunger sensation developed which was regarded as a protein-hunger sensation. The fasting gastric acidity again decreased and the protein-hunger sensation disappeared with protein realimentation. If these findings on man also applied to rats, it seemed that the amount of ulceration that was likely to occur in rats, solely as a result of intermittent starvation, would depend considerably upon the amount of protein in the diet fed on feeding days. Besides this, it seemed possible that ulcers might develop in rats as a result of sufficiently prolonged

*From the Department of Physiology, University of Chicago.
Submitted January 30, 1937.

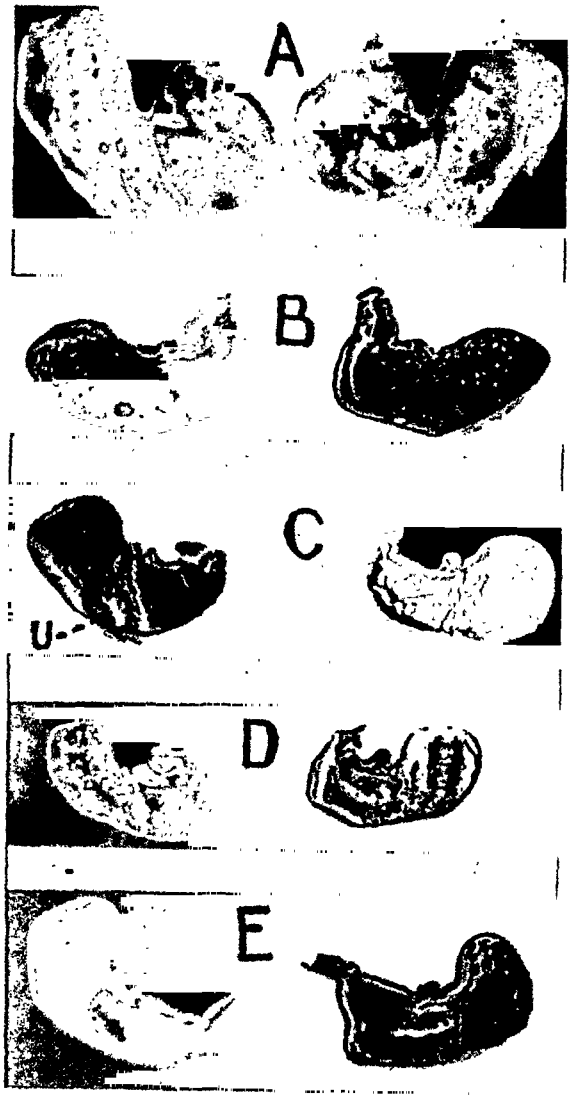

FIG. 1. Showing gastric ulceration in rats starved or fed diets deficient in protein. A, male starved 2× days, then fed adequate diet 28 days, next starved 2× days, then fed again 35 days and finally starved to death in 3× days; final age 4×2 days and weight 178 gm.; marked ulceration of prostomach with some extended perforation and stricture of pylorus and erosion of main stomach. B, female, fed only white bread 27 days, last after 24 hrs before death; ate all but half of one, last 2 weeks kept in hot environment, marked ulceration of prostomach with little bleeding. C, female, 16 days on diet of 100 parts lard, 10 parts dried yeast, 4 parts salt mixture and 100 parts cellulose flour, next after 19 (terminal) on 5th day prostrated, appeared to be terminal when sacrificed; perforated ulcer. U, penetrating into liver. D, male, died after 12 days starvation. Early appearance of lesions (at) after that temperature 12° C.) was still too low to prevent serious feeding. E, female, starved 2× days, then fed 20 days, next starved 2× days and then sacrificed after 6 days on adequate diet, showing healing of ulcer well on its way.

starvation or protein restriction alone and ulceration thus produced could evidently be regarded as objective evidence of protein-hunger carried to a pathologic extreme.

As already indicated in a preliminary report (5a), we tested our first inference experimentally by starving 35 rats every other day or during alternate two-day periods and feeding some of the rats diets adequate in protein and others diets low in protein on feeding days. As a result, some rats developed ulcers in the prostomach within three weeks even when a diet adequate in protein was fed on feeding days but all rats that were intermittently starved and fed diets with only about 3% protein for more than two weeks developed ulcers in the prostomach. No ulcers were found in the prostomach of 175 stock (control) rats.

These results led us to extend our study to determine the effect of more prolonged starvation, protein restriction without starvation, diets high in protein, diets differing in the main type of protein used, high and low carbohydrate or fat diets, watery diets, diets deficient only in vitamin A or B, and diets to which salt, pepper, mustard, acetic acid, alcohol, hydrochloric acid or antacid salts were added. The effect of adding various kinds and amounts of roughage to some diets was also investigated. In addition to this, the effect of exposure to high and low environmental temperatures was observed. More recently, tests were made to determine the value of histidine (Larostidin) as a preventive of ulceration. In nearly all cases 8 or more rats were used for each specific test. Altogether 1704 rats and 77 mice, including 230 stock (control) rats and 7 stock mice, were used. Most of our rats were white rats but 73 were black-and-white.

Prolonged starvation (with water given) proved to be our most effective method of producing ulcers in the prostomach of rats (Fig. 1-A, D and E). Some ulceration was usually observed when rats were sacrificed after 4 days of starvation but great individual variations occurred. In a few adult rats ulcers were not present after 7 days of starvation while in one young rat well developed ulcers were found after only 36 hours of starvation. The impression was that diets entirely devoid of protein would produce ulceration about as easily as starvation but we used powdered yeast as the source of vitamin B in our synthetic diets and, when such diets included 5% or 6% yeast to make them substantially adequate in vitamin B, they contained from 2% to 3% yeast protein (which is rich in essential amino-acids). All of 10 rats fed a diet with 6% powdered yeast as the sole source of protein, but otherwise adequate, had ulcers in the prostomach when they were sacrificed after from 13 to 21 days. Diets containing larger amounts of yeast caused less ulceration when fed for only 2 or 3 weeks. Five out of 12 rats had ulcers in the prostomach after having been fed 14 days with a diet containing 20% gelatin as the chief source of protein but otherwise quite satis-

FIG. 2. Section through large prostomach ulcer with adhesion to and penetration into liver, shown in Fig. 1—C, U. E, edge of epithelium of prostomach (healing some overgrowth).

factory. Nineteen out of 27 rats fed only white bread (which contains about 10% protein) showed ulceration of the prostomach within 4 weeks. Rats that did not get ulcers from a diet of white bread usually ate more and thus ingested more protein than rats that developed ulcers. On the other hand, rats that developed ulcers on diets adequate in protein ate very little. This occurred when the diets were deficient only in vitamin A or B but such diets did not lead to ulceration as soon or as uniformly as diets deficient in protein. Diets low in protein caused ulceration whether high in carbohydrate or high in fat. Some rats manifested an apparent nausea after ingesting diets high in fat and low in protein—they gagged and salivated after eating as if about to vomit. Such reactions were never noticed when diets high in fat but adequate in protein were ingested. Wet low-protein diets (thin pastes made by adding large amounts of water to dry food or diets of fresh vegetables only) caused little or no ulceration even when fed as long as 7 weeks, although ascites was produced in most cases. The addition of table salt to such or other diets did not cause any definite increase in ulceration. Mustard added to a deficient diet, such as a white bread diet, seemed to make it more adequate or more palatable to rats. Pepper added to diets led to a reduction in the food intake but the ulceration which followed could not be ascribed to irritation by the pepper. Hydrochloric acid as well as sodium bicarbonate added to diets usually led to a reduction in the food intake but the acid produced more acute erosion and ulceration and the alkali led to some hyperkeratinization about the ulcers that developed in the prostomach. Alcohol added to the diets caused pylorospasm and gastric retention with ulceration (5c, d). The most striking ulceration occurred when pregnant rats were fed diets deficient in protein (Fig. 1-B, C and Fig. 2).

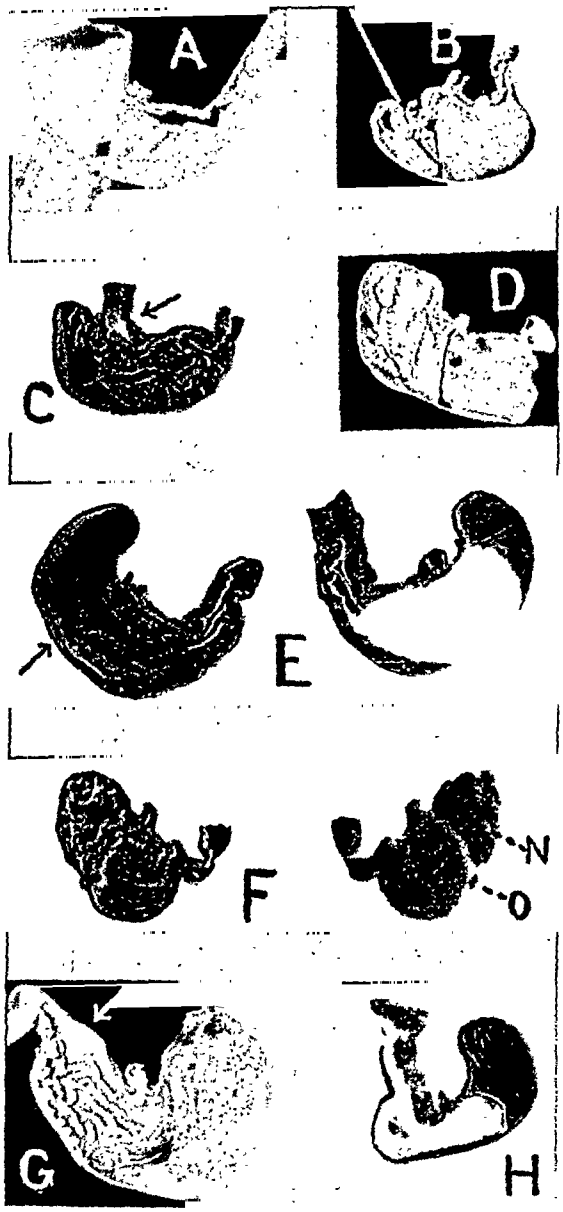

Fig. 3. Showing various gastric lesions in rats. A, male, starved 7 times from 8 to 18 days, total 94 days, last 18 days high fat and adequate protein diet with dog hair, sacrificed; perforated ulcer with adhesion to abdominal wall, hair in this ulcer and in cornified nodules nearer cupola of prostomach. B, female, died after 10 days starvation following 13 days white bread diet; ulcer in cupola perforated with invagination and thickening of prostomach. C, male, sacrificed after 5 months on white bread, last 3 months with cellulose flour; marked ulceration of esophagus, hypertrophy of mucosa of main stomach due to use of bulky material. D, male, died without showing interest in eating after 8 days starvation following 40 days on white bread with cellulose flour; ulceration probably parrlyzed functioning of stomach. E, female, sacrificed after 5 months adequate diet with dog hair; raised 3 litters in nests of dog hair; dog-hairball practically fills stomach; arrow indicates small ulcer due to greatly decreased food intake. F, inner and outer aspects of ventral half of stomach; female, starved 8 times from 5 to 7 days, final 32 days diet high in fat, low in protein (6%) and with dog hair, died; O, large epithelial cyst; N, cornified nodule—section shown in Fig. 4—B. G, male, starved 9 and 10 days, then 2 months diet high in protein plus HCl, sacrificed; severe diffuse erosion of prostomach (due to HCl) and multiple craters in antrum. H, male, 2 months on washed bran plus casein and gluten, final month kept cool, died; diffuse erosion with bleeding of main stomach.

Pappenheimer and Larimore (6) found that 61% of rats fed a diet containing 95% white flour developed ulcers in the prostomach but they apparently did not suspect that the protein inadequacy of the diet, of which they were fully aware, could be responsible for the ulceration. They attributed the ulceration to mechanical irritation or infection by ingested hair. We found hair in the stomachs of many rats and well formed rat-hairballs in 13 rats without any relation to ulceration. We also added cut up, coarse dog hair to the diets of some rats and thus produced dog-hairballs in the stomach of 3 rats but, with a diet adequate in protein, a shallow ulcer developed only in one case where the dog-hairball became so large that it finally interfered with the food intake (Fig. 3-E). However, when dog hair was fed with a diet deficient in protein, hair sometimes penetrated into the denuded (ulcerated) areas. In a few rats that were later again fed diets adequate in protein some ulcers healed with bristling stubs of dog hair healed *in situ*! McCarrison (7) observed gastric ulcers in rats fed diets such as were used by certain natives of India among whom peptic ulcers frequently occurred. These diets were low in protein. A number of other investigators reported that gastric ulcers developed in rats as a result of vitamin deficiencies but, as already suggested, our observations indicated that ulceration under such circumstances is due to a lowered food (protein) intake. Peptic ulcers also must have developed in many instances in rats and mice used in studies of the biological value of proteins, particularly of proteins markedly deficient in some essential amino-acids, but ulcers were evidently not even looked for. The question now is: Are the apparently essential amino-acids essential

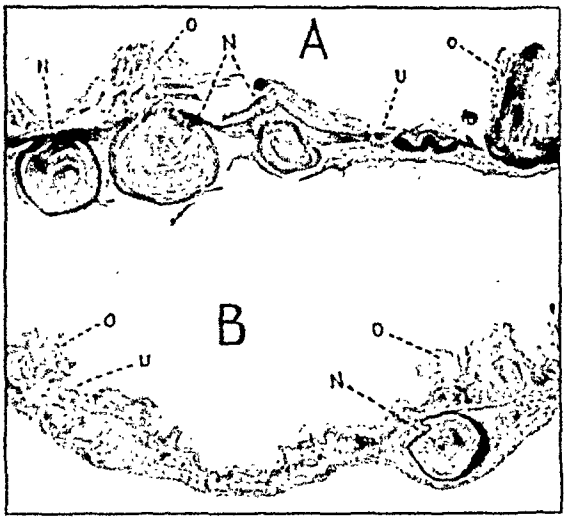

Fig. 4. Sections showing marked morphological changes following ulceration in prostomach of rats. A, female, black-and-white, died after 58 days on white bread with cellulose flour; with numerous cornified nodules (N) mainly in cupola of prostomach; O, epithelial overgrowth, U, ulcer. B, section through nodule (N) shown in Fig. 3—I; white rat.

primarily for growth, as has heretofore been assumed, or are they essential primarily to assure a quantitatively adequate food intake by preventing peptic irritation or ulceration?

The environmental temperature was found to be an important factor in determining the degree of ulceration that was likely to occur in starving and malnourished rats. The desirability of a relatively high temperature for the comfort of starving and undernourished animals was already appreciated by the senior author of the present report because of disagreeable personal experiences while fasting or using restricted diets during cold weather. Accordingly, a room was fitted with electric heating units to supplement the regular heating facilities and to automatically maintain temperatures at the desired levels. Starving animals were usually kept in this room at from 28° C. to 31° C., depending upon their condition. For experimental control, some rats were also kept in a modified ice box, especially during hot weather, to note the effect of relatively low temperatures (15° C. to 20° C.). It was found that starving rats died much sooner in a cool environment than when they were kept warm. A cool environment or chilling caused diffuse peptic erosion and increased the bleeding of lesions in the stomach. In terminal stages, it also caused diffuse bleeding mainly in the middle half of the small intestine, without previous erosion or ulceration. Besides this, chilled rats passed bloody urine. On the other hand, little or no serious bleeding occurred in the digestive tract of rats that were kept warm. At 28° C. to 31° C., we were able to starve rats from 15 to 39 days on 42 occasions, with more striking ulceration than could have been obtained at lower temperatures.

The lesions that develop in the prostomach of rats have already been described in more or less detail by others (1, 2, 6) and we agree with the German investigators (1, 2) that peptic erosion by acid gastric juice is responsible for such ulceration. Figures 1, 2, 3 and 4 show various types of prostomach ulceration. It will be noted that the largest prostomach ulcers or the most severe ulceration (including perforations in 4 of our rats) occurred on the ventral half of the stomach near the ridge dividing the prostomach (the non-acid-secreting part of the stomach) from the main stomach or ventriculus (the acid-secreting part). The ventral half (the halves on the left in Fig. 1) is the lower half of the stomach in the position most commonly assumed by rats. Gastric residues would therefore tend to gravitate into and remain most directly in contact with this part of the stomach. The cupola, dome or fundic portion of the prostomach was also highly vulnerable (perforations in one rat — Fig. 3-B — and in one mouse). Ulceration often occurred on the ridges of the rugae formed by the contracted stomach (Fig. 1-D) but the stomach was usually relaxed in rats that had been kept warm. Ulceration about the esophagus was also common (Fig. 3-C and Fig. 5-A). In fact, the entire prostomach of rats and mice might be regarded as a dilated portion of the esophagus which is considerably exposed to the acid gastric juice when the food intake is inadequate.

LESIONS OF THE MAIN STOMACH

Ulceration of the main stomach of rats was not as easily produced as ulceration of the prostomach and the lesions that developed in the main stomach were different. Thus among the 175 control rats referred to earlier in this paper, 3 rats had "craters" in the antrum although none of them had ulcers or other lesions in the prostomach. But such "craters" (Fig. 3-G) can hardly be regarded as ulcers. We have, however, come to recognize them as an early stage of the most common type of ulceration in the main stomach, antrum and prepyloric region of rats. These lesions simply have a crater-like appearance and usually consist of a slightly elevated and pale or white (mucus-secreting ?) ring from 1 to 2 mm. in diameter with a "pin-point" depression in the center. Sometimes the depressions were not evident and sometimes numerous depressions appeared without surrounding rings or crater-like rims. Under the microscope, sections of typical craters generally showed only a depression in an otherwise intact mucosa but, with transillumination, the pin-point depressions looked like potential perforations (Fig. 5-E, F). The centers of some craters usually bled when bleeding did not occur elsewhere after the animals had been chilled.

Starvation and diets with less than 4% protein, which often gave rise to marked ulceration in the prostomach, usually caused only a little erosion in the main stomach and rarely gave rise to crater formation. This may have been due to the fact that it generally took longer for craters to develop in the main stomach than it took for rats to die from starvation or from extreme protein restriction. However, a diet of white bread (the protein of which is deficient chiefly in lysine) led to prepyloric crater formation in about 70% of the cases in 2 or 3 weeks. When white bread was fed exclusively for about 4 weeks or longer, the centers of some of the craters were usually more or less eroded and presented the appearance of ulcers. The addition of 25% or more of cellulose flour to diets somewhat inadequate in protein often increased crater and ulcer formation (Fig. 5-A and Fig. 6-A). The craters found in the 3 control rats referred to above were very likely due to the feeding of too much bread

or corn. Our observations also showed that a diet with gelatin as the main source of protein has a marked tendency to initiate the development of craters in the acid-secreting part of the stomach.

A particularly striking type of lesion of the main stomach was a "punched in" ulcer-like lesion (Fig. 5-B) seen in two rats that were fed only white bread while pregnant. Such lesions probably correspond to the punched out round ulcers that have been produced in dogs but, in our rats, the areas surrounding these lesions were markedly discolored (blue or purple) and this suggests that circulatory disturbances occurred in these areas. However, we believe that the apparent interruptions in the circulation in these areas were a consequence and not the cause of these rapidly developing lesions. Sections under the microscope again showed that the mucosa was also intact in and about these ulcer-like lesions. This and the histological findings concerning the more common craters referred to in the preceding paragraph support the frequent claim that gastric ulcers, such as are seen in humans, do not begin as erosions of the mucosa. Further study is needed to determine whether the mucosa remains intact while a considerable amount of tissue beneath it is destroyed or whether it alternately erodes and heals.

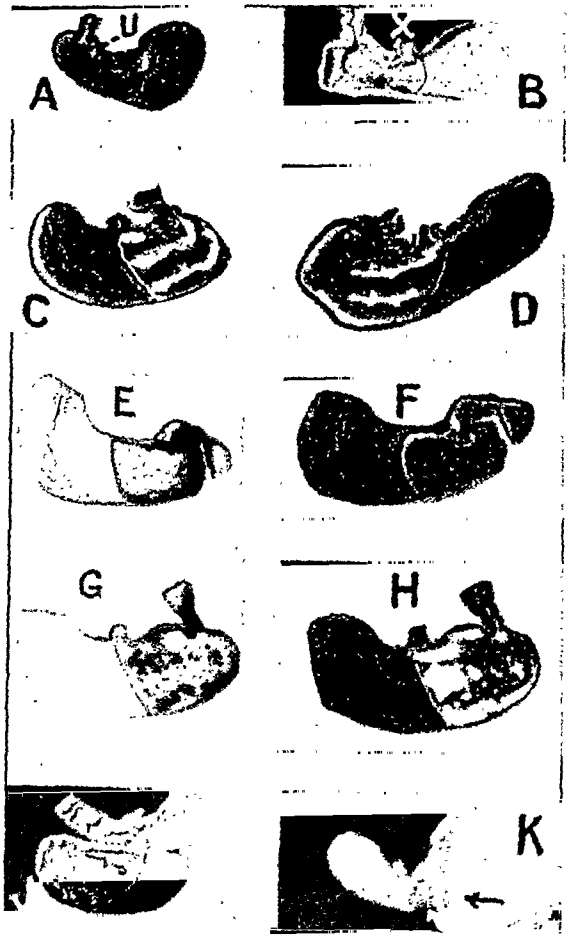

Fig. 5. Showing chiefly lesions in main stomach of rats. A, female, fed white bread with cellulose flour 14 days, sacrificed; U, ulcer in antrum at incisura—section shown in Fig. 6—A; also large ulcer at oropharynx. B, female, fed only white bread 31 days; cast litter (removed) 4 days before death, X, "punched in" ulcer-like lesion in discolored area on rugæ in center of main stomach. C, male, fed diet 3 weeks with 43% casein plus cellulose flour and HCl, last 6 days in cool environment, died; roughening of prostomach (due to acid) and marked erosion of rugæ in main stomach. D, male, fed mainly bran 6 weeks, last 3 days cool (15° C. to 23° C.), died; marked erosion of rugæ and numerous pin-point depressions in main stomach. E, transillumination of F, male, 3 months low protein diet—mainly white bread and cellulose flour, last month hot weather and given some alcohol; numerous pin-point depressions in main stomach—seen best by transillumination. G, transillumination of H, female, 6 weeks high protein diet with cellulose flour, last 6 days cool, died; erosion and bleeding of main stomach with pin-point depressions and fissuring—more evident by transillumination. J, male, 6 weeks coarse washed bran plus mainly carbohydrates, last 7 days kept warm, died; scooped out lesions in main stomach without much bleeding. K, young female, died after 36 hours starvation, final weight 34 gm.; diverticula in antrum similar to diverticula found in other young rats fed mainly bran.

The study of the development of lesions in the main stomach of rats is additionally complicated by the fact that diets relatively high in protein (with about 35% or more of protein) usually cause inflammation and other injuries, especially when coarse materials are fed. Bran had an effect similar to that of a diet high in protein and with cellulose flour and hydrochloric acid added (Fig. 5-C, D). Besides inflammation, excessive amounts of protein with roughage produced severe erosion, fissuring, pin-point depressions and craters, scooped out lesions and thinning of the wall of the main stomach with the formation of diverticula in the antrum in some cases (Fig. 3-G, H and Fig. 5). The diets producing these lesions eventually led to the death of the animals by gradual starvation but the prostomach under these circumstances usually remained intact.

DUODENAL LESIONS

We already stated elsewhere (5d) that we were unable to produce duodenal ulcers in rats. Starvation and diets low in protein, as well as a diet of only white bread or with cellulose flour added, left the duodenum intact. Diets containing excessive amounts of protein often caused inflammation of the duodenum. Diets consisting of 50% or more of bran came closest to producing typical duodenal lesions in rats. That is, such diets sometimes produced erosions in small, sharply defined areas in the duodenum, 2 or 3 mm. from the pylorus. Occasionally, two eroded areas developed opposite one another, simulating "kissing" duodenal ulcers. Although duodenal ulcers did not occur in any of our rats, they were found to develop in mice (Fig. 6-B). Among 70 mice, 13 had duodenal lesions, one of these had multiple duodenal polyps, 4 had "kissing" erosions or ulcers and at least 5 had ulcers. T. P. Sun (8) previously reported that the duodenal mucosa of mice becomes denuded in 24 to 64 hours by starvation. It seems significant that both mice and humans develop duodenal ulcers and both have a gall bladder while rats do not appear to develop duodenal ulcers and also have no gall bladder. This suggests a relation between duodenal ulceration and bile flow, and bile flow may in turn depend upon liver function and protein metabolism (5d, 9).

ATTEMPT TO MAKE ULCERS CANCEROUS

After finding that ulcers could be produced easily in the prostomach of rats by starvation or protein restriction, we tried to make them chronic or cancerous. It was thought that mechanical irritation by a diet containing bran should suffice to prevent the healing of ulcers but prostomach ulcers healed in all cases where large amounts of bran were fed for a few weeks. We therefore tried to produce chronic or cancerous lesions by subjecting rats to repeated periods of relatively prolonged starvation or protein

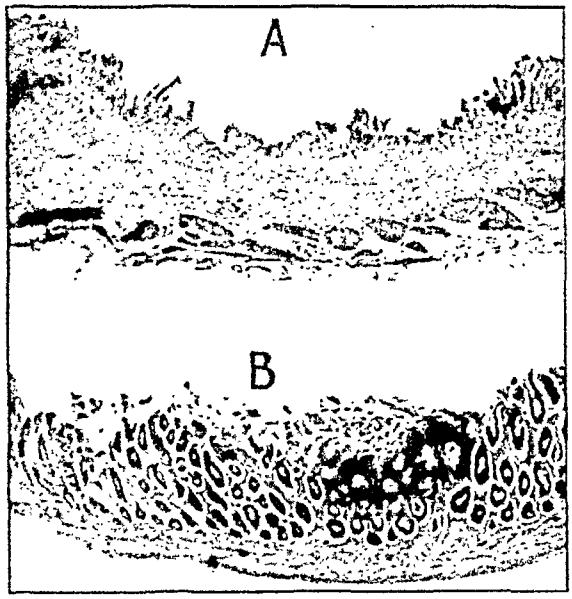

Fig. 6. Showing, A, section of ulcer in antrum of stomach indicated in Fig. 5—A. U.; and B, section of duodenal ulcer in mouse starved 36 hours after 9 days on ground washed bran plus 13% corn oil; similar lesion opposite this in duodenum.

restriction, with more or less adequate realimentation between such periods. As a result, some degree of cumulative ulceration and epithelial overgrowth was often produced. In some cases, epithelial cysts and cornified nodules developed in the ulcerated prostomach (Fig. 3-F; nodules also appeared in the stomachs shown in Fig. 1-A and Fig. 3, A). The cornified masses were due to downgrowths of the squamous epithelium in ulcers and resembled the "cancerous" changes produced by Fibiger (10) by feeding rats spiroptera or cockroaches infected by spiroptera. However, Fibiger fed his rats white bread exclusively and was able to produce the "cancerous" changes only in black-and-white rats. We also noted that cornified nodules developed most easily in black-and-white rats *and precisely when they were simply fed only white* bread (Fig. 6-A). But similar nodules also developed in white rats as a result of repeated starvation or protein restriction (Fig. 6-B). Fujimaki and other Japanese workers (11) reported the finding of "cancerous" changes in the prostomach of white rats and mice fed various diets but, like Fibiger, they failed to note any relation of such changes to protein deficiency and ulceration. As a matter of fact, none of the observed morphological changes were ever cancerous and experimental cancer from ulcer still remains to be produced.

HEALING OF ULCERS

Most ulcers produced by starvation or protein restriction healed completely when diets adequate in protein were fed but some cornified nodules and small cysts tended to remain. The healing response to a single meal of adequate food after a prolonged fast was striking. This was observed when some rats died within a few hours after they voraciously devoured a large amount of food immediately after a protracted fast. Death was probably due to increased bleeding of ulcers or other lesions and the extra tax of the excessive food intake on a feeble organism. (Humans suffer similarly—sometimes die—as a result of dietetic excesses after prolonged food restriction). In the rats, excepting for the gross lesions, the mucosa of the stomach and small intestine to within a centimeter or two of the head of the column of recently ingested food always appeared much more like normal than the part of the intestine that had not yet been reached by food. Nevertheless, the complete healing of some prostomach ulcers evidently took a little longer than their formation by our most direct method — prolonged starvation. *Otherwise a cumulative ulcerating effect* could not have occurred, as it did, when rats were intermittently starved about 4 days or more at a time and fed freely during periods of only similar length.

The value of a diet high in protein, as an aid in the healing of gastric lesions, seemed indicated by the finding of Harvey and Howes (12) that such diets help to heal experimental wounds of the stomach of rats but evidence was obtained in our study that an excessive protein intake, immediately after a period of protein restriction, often has a detrimental effect at first. Rats that had more or less free choice and spontaneously selected milk and bread as the principal food immediately after prolonged fasting seemed to fare best. However, as already indicated, prostomach ulcers frequently healed even when bran was fed. This may have been due to the protein supplied by bran (which is fairly rich in essential amino-acids), its acid-binding power or the shifting of the acid gastric juice burden from the prostomach to the main stomach and duodenum. Pregnant rats, *which generally developed* the most striking ulceration with inadequate diets, showed more or less healing shortly after casting their litters, which were always removed in these cases. This was apparently a consequence of the protein intake involved in eating the placentae. In tests on 13 rats, histidine (0.5 to 1.0 c.c. Larostidin daily per rat) did not prevent ulceration of the prostomach when a diet low in protein was used. An adequate supply of other amino-acids seems to be as important as an adequate supply of histidine. On the other hand, our results did not confirm the finding of Windwer and Matzner (13) that prostomach ulceration is increased by histidine (Larostidin).

PEPTIC ULCERATION AND PROTEIN-HUNGER

Our studies on rats and mice would seem to make it obvious that in these species there is a direct relation between peptic ulceration and protein-hunger. That is, rats and mice evidently eat a certain amount of protein at least partly *in response to peptic stimulation* or titillation and to prevent peptic irritation or ulceration. The same mechanism apparently also compels rats and mice to eat a certain amount of biologically adequate protein. Whether ulceration occurs because of a lack of sufficient acid-binding protein in the diet (or in the stomach) or because of an increase in gastric acidity following protein restriction or because of a lowered resistance to ulceration or a combination of these possibilities, a relation between peptic stimulation, irritation or ulceration and protein-hunger or amino-acid-hunger would still be indicated. In addition to this, we had evidence that an excess of protein also tends to produce gastric lesions and this suggests a mechanism which would normally limit the protein intake. These findings therefore help to ex-

plain why rats and mice tend to select a moderate and practically optimum amount and biologically adequate protein when they have free choice (14).

The difference between these species and other species is very likely only one of degree. There is no doubt that carnivores like dogs can tolerate both starvation and an excessive protein intake better than rats, mice or humans but it is not so certain that dogs or humans can tolerate protein deficiencies much better than rats or mice. Obviously, allowances must be made for differences in metabolism, length of life, etc. But Weech (15) observed ulceration in dogs fed diets low in protein. Chittenden and Underhill (16) found duodenal ulcers in dogs fed biologically poor protein. Ivy (17) noted that cachectic dogs were more likely to have gastric lesions than well nourished animals. Koschtojanz (18) found that the first phase of gastric secretion is increased in dogs by a diet without meat and Pankratjew (19) reported the perforation of a gastric ulcer in a man on a hunger strike. On the other hand, a fairly dependable mechanism normally regulating the protein intake is indicated by the fact that most humans, as well as omnivorous animals, tend to use a moderate and practically optimum amount and adequate types of protein when free choice is possible (4, 20). It seems that the question has not been whether such a mechanism exists but rather what it consists of, what its limitations are, how it becomes disorganized and how it may be controlled.

In our opinion, the failure of investigators to note the relation between protein or amino-acid deficiency and peptic stimulation, irritation or ulceration long ago is due to the neglect of a sufficient study of the factors influencing the fasting gastric secretion. This apparently began as a result of the classical work of Pavlov (21) in which he demonstrated that *the lavaged stomach of a well fed dog does not secrete gastric juice without chemical or psychic stimulation.* This dictum led many uncritical followers of Pavlov to maintain that *acid gastric juice is never secreted under any other circumstances by the normal "empty" stomach,* including that of man. Carlson (22) pointed out that there was a more or less continuous secretion of acid gastric juice in normal human subjects, as well as in some animals, and that the acid juice seemed to give rise to an appetite-like sensation in man. The relation of the continuous, basal or fasting gastric secretion to hunger was next investigated by the senior author of the present report in a study made upon himself. As a result, periodic variations in the fasting gastric secretion or contents were found to occur and to be related to the periodic changes in fasting gastric motility (3a). This finding was confirmed by Hellebrandt (23). Thus far others do not seem to have undertaken any studies on man that might confirm our observation of a relation between variations in protein intake and the fasting gastric acidity (3b) or between the fasting gastric acidity and protein-hunger (4) but the results of our studies on rats and mice seem to amply support our earlier findings on man. The evidence thus far published in support of the theory of Weiss and Aron (24) concerning the rôle of amino-acid deficiencies in gastro-duodenal ulceration does not seem to have been convincing (25) and, in any case, could hardly be directly applied to our own findings.

SUMMARY

Ulceration of the prostomach and main stomach of rats and mice and ulceration of the duodenum of mice but not of rats was found to occur as a result of starvation or diets deficient in protein or in essential amino-acids.

Ulceration thus produced is regarded as objective evidence of protein-hunger or amino-acid-hunger which has been carried to a pathologic extreme.

The Pathogenesis of Senile Osteoporosis

Relations to Morbus Cushing and Basophilia of the Anterior Pituitary

By

ERNST LYON, M.D.

JERUSALEM, PALESTINE

ACCORDING to Schmorl and Junghanns, osteoporosis is one of the most frequent changes, affecting the whole bone system. Disturbances of nutrition, changes in the internal secretion, cachectic diseases, chronic biliary fistulas, etc., were assumed to be exciting factors. "Puerperal" and "Hunger" osteoporosis are well-known and have often been described. Osteoporosis is chiefly a disease of old age.

In a series of osteoporotic pictures the changes are roentgenologically and anatomically identical. Senile osteoporosis, as well as puerperal osteomalacia, takes up a special position in a clinical sense. Senile osteoporosis develops in the whole bone system. It is neither all the bones nor always the same ones that are attacked. The processes in osteoporosis are to be observed with special distinctness in the vertebral column.

Senile osteoporosis develops when the bone apposition ceases, while decompensition is normal or increased. Changes of form and structure are to be found. In respect the form changes of the vertebral column, here only the "hour-glass" and the "fish-vertebra" shapes, the flattened and wedge-shaped vertebrae should be mentioned. The structural changes, especially in the vertebral column, are represented by diffuse porosis. The histological findings show a porotic frame of spongiosa. In contrast with the normal spongiosa, the trabeculae are scanty, thin and more perforated. The spongiosa weakened in its solidity is, in addition, brought to atrophy by the physiological pressure of expansion of the intervertebral disk, the gelatinous nucleus being intact.

As to the *bone changes themselves*, we should not think that the relations are too simple. The senile increase of bone brittleness has its origin in essence in the physico-chemical fact of aging (Schade). Under *normal conditions*, however, a decrease of the phosphates in the bone-ash can also be observed; but in a still larger amount this can be found in senile osteoporosis (Tannhauser). Etienne and Douplais found in senile osteoporosis a strongly negative lime-balance, decrease in the *Ca* content of the bones and an increase in the *Ca* content of the soft parts in opposition to the rule. In any case, this osteoporosis differs even in the chemical-analytical findings from the malacic bone diseases, such as rickets and osteomalacia.

Regarding the *symptoms of senile osteoporosis*, we can only mention here that everything that is characteristic of senile osteoporosis may also occur in other diseases. In the forefront, we find signs of senescence, pains in all possible parts of the body, conditions of weakness. In the *X-ray picture*, the chief finding is that the bones are deficient in lime. In some (not in all) cases we find a striking "decrease of resistance"; the disposition towards disease is increased, the struggle against infectious diseases rendered difficult.

Much has been written on the *pathogenesis* of senile osteoporosis. Hitherto investigators have not succeeded in clarifying the subject. Kienbock recently, again made an attempt to explain the osteoporotic diseases as "degeneracy diseases," as a dysplasia and a dystrophy of the skeleton. He assumes a strong and widely spread inferiority of the skeleton to be the exciting cause. Difficulties arose even in trying to fix the nomenclature and classification of the disease, the origin of the senile osteoporosis not being clarified. Some observers differentiate between senile osteoporosis and senile osteomalacia and acknowledge a special form of osteoporosis and a special spontaneous and another form due to hunger. It has even been believed that there are transition forms of senile osteomalacia and osteoporosis. The fact that in senile osteopathia we frequently find endocrine symptoms ought to give us the right for the designation of osteomalacia. Thus symptoms of Graves' disease, myxedema, tetany, etc., were noted, furthermore there have been noted disturbances of the parathyroid, of the pituitary gland and of the genital glands. The symptom regarded as characteristic of osteomalacia, that of the subject growing smaller, can be found in osteomalacia as well as in osteoporosis. But the therapeutic effect of phosphoric codliver-oil, of calcium and vigantol is not proof convincing enough to be employed as a dependable means of distinction in the differential-diagnostical sense. In like value can brittleness of the bones and bonebending be used as a typical sign for the one or the other form. At the moment, senile osteomalacia and senile osteoporosis are looked upon as a unity.

The calcium, as well as the mineral metabolism in general, are known to be under the regulative influence of hormones. The parathyroid gland plays a great part in the regulation of calcium metabolism. The involutional processes, too, are regulated by the endocrine apparatus, and complex disturbances of the endocrine system make the physiological process result in a clinical disease of the bone-system (Alwens). But we have not gained much by reciting these frequently-repeated statements. For we have to deal with a complex hormonal process due to a reciprocal influence of the glands and mutual advancement and inhibition by their own products. Endocrine disturbances are regularly pluriglandular. Mostly, in theoretical analytical considerations, only the chief hormonal effect is pointed out. Recent findings have been established which (also in orteoporosis) set aside general points of view and point in a certain direction. New conditions of disease of the endocrine organs having been observed in recent years, the frequent dependency of osteoporosis as a consequence of diseases of certain endocrine organs could be stated. Thus, Jamin described in a woman of postclimacteric age after the cessation of ovaric function a form of senile change, going along with hyphosis, obesity, hypertension,

cardiac weakness and hypertrychosis. Jamin indicates the similarity of this complex of symptoms to "Cushing's Disease"; plain visual observation shows these women to have full-round faces, such as are noted in the syndrome described by Cushing.

A patient of this type is described as follows: April 1, 1934. Barbara F., aged 67, 157 cm. tall, 78.5 kg. in weight, has become more corpulent during the last few years and has gone from one physician to another because of backache. Had dyspena, reddish, somewhat spongy, full- round face; broad red striae on abdomen and thighs, dilatation of the left heart, blood-pressure: 190/140 mm. Hg., tympanitic abdomen, traces of sugar in the urine. Blood: hemoglobin 90%, erythrocytes: 5,200,000, blood picture without any peculiarities. Blood sugar 190 mg. per cent. Blood calcium, 9 mg. Kyphosis of the thoracic vertebral column, first lumbar vertebra sensitive to pressure. *X-ray of the vertebral column* (lateral view) shows a pronounced lordosis of the lumbar part and kyphosis of the thoracic part, the vertebral bodies are poor in lime; only at the superior and inferior edges stripes of a somewhat increased lime content are to be found, the first lumbar vertebra is flattened and wedge-shaped, the intervertebral disk lying beneath has become smaller. In the upper part of the first lumbar vertebra a large "Knorpelknoten."

Diagnosis: adipositas, hypertension, plethora, osteoporosis, hyperglycemia, glycosuria. *Course:* Extensive improvement of the backache and loss of weight up to 5 kg., followed in two months after no therapy but roentgen-irradiation of the pituitary gland.

Differentiation between cases with constitutional obesity, hypertension and a more or less pronounced osteoporosis and an obesity of the type of Cushing (osteoporotic obesity of Askanazy) is impossible in the borderline cases. In older women obesity, hypertension and osteoporosis are no rare event. There are also benign forms of Cushing's syndrome in which some of the symptoms are absent and which remain stationary.

The picture of "pituitary basophilism" described by Cushing is known to be a syndrome in which basophile adenoma of the anterior pituitary is joined with obesity of face, neck and body, with hypertension, plethora, hypercholesterinemia, striae, osteoporosis of the skeleton (in more than 70 per cent of the cases) and sexual hypofunction. Frequently, there is a disposition towards infectious diseases manifesting in threatening outbursts. In some cases, a series of symptoms is absent; the process can proceed quickly; however, it can also remain stationary over a long period.

April, 1935: A typical case of Cushing's syndrome under my own observation, showed the following main features: A young German man, born in November 26, 1911, 8 years in school with good certificates. Afterwards he left the occupational school with very good results. From his 13th year he grew bigger. From his 19th year he has complained of becoming fatigued. From 1930 up to 1935 the faitgue and feebleness increased still more; frequent bronchitis and rheumatic affections. In his 17th year, slight dizziness; these attacks increased from year to year. He often falls down and loses consciousness for a short time. On this account, a professor of internal medicine thought this picture to be that of epilepsy and proposed to have the patient sterilized. In order to discuss this affair the man called on me (May, 1935), as I had observed in him a considerable hypertonia (210 mm. Hg.) of a permanent character in 1933.

Findings in *April, 1935:* Heavy young man, 187 cm. tall, 104.5 kg. in weight; marked obesity of body and face without participation of the extermities; the face somewhat spongy, slightly reddish-brown in color, scanty hair on the head; acrocyanosis; broad red striae of the skin of the abdomen, the shoulders, the upper arms; thoracic organs: clinically and roentgenologically without any peculiarities; blood pressure 170/110 mm. Hg., the electrocardiogram was normal; abdominal organs without any peculiarities. The blood-picture shows an increase of hemoglobin up to 115 per cent, erythrocytes: 5,320,000; in the differential blood-count there was lymphocytosis; sedimentation rate 5/14 mm. test for lues, negative; blood sugar in the serum, 111 mg. per cent; calcium content, not increased; the blood sugar tolerance test there was a rise up to 154 mg. per cent, with 150g of grape sugar; three hours later return to fasting level. The basal metabolism reduced to 9%. Protein tolerance: within 1½ hours rise to +7%. In the urine was normal as was the renal function. X-ray picture: on both the *capita humeri*, osteoporotic processes were seen, together with a slight deformity. X-ray picture of the vertebral column showed a more pronounced waist-shape of the lumbar vertebrae, the markings of the vertebral bodies being hazy; spina bifida of first sacral vertebra; X-ray of the skull showed a normal sella turcica; somewhat hazy markings of the skull bone in the upper area, this fact perhaps speaking in favor of an early osteoporosis. Genital organs normal.

Deep roentgen irradiation of the pituitary gland resulted in a loss of weight and a diminishing of the blood pressure. Then the patient gained in weight again. In the beginning of February the dizziness occurred again more frequently than usual, but only for one minute. At night the patient becomes blue from these attacks, in the day time he quickly improves. After the pituitary gland had been irradiated again more intensely, he lost 10 kg. in weight, and, at the end of February weighed 108 kg.

When comparing the disease of the woman, aged 67, with the severe disorder of this young man, the similarities become apparent. The case of the young man is—so to say—the exaggeratedly developed reflection of the benign stationary form of the post-climacteric woman. Kylin is right in saying that, in such cases, the difference is that in Cushing's syndrome the symptoms have been more worked out by nature and are therefore more striking. However, the main symptoms: special type of obesity, arterial hypertension, plethora, osteoporosis, etc., are the same. The cases reported indicate, with their like features, a relation between Cushing's hypophyseal adenoma and the obesity accompanying hypertension and osteoporosis, occurring in older women. According to Raab, adenoma of the anterior pituitary reflects in an exaggerated way the chief signs of old age; close study would perhaps be able to give an insight into the physiology of age. Kylin points out the similarity between hypertension diseases, occurring after menopause, and the symptoms of the basophile adenoma of the pituitary gland, and he considers "essential" hypertension to be the consequence of a hyperfunctional condition of the anterior pituitary due to a reduction of the inhibiting influence of the generative glands. Jores comes to the same conclusions; he found in the serum of some people, affected with hypertension, substances calling forth the same histological changes and having the same chemical qualities as the corticotrope and adrenolotrope hormone of the anterior pituitary. Berblinger, however, refuses to look upon the basophile increase in so simple a way as its the anatomical expression of the permanently increased formation and effect of vasopressin, and to ascribe the essential hypertension merely to that fact. Kraus thinks that the basophilia of the pituitary gland in Cushing's

syndrome is not the exciting cause of the disease but only a secondary change of the pituitary gland, occurring in the course of the disease. In opposition to which Berblinger looks upon the basophile adenoma, as well as the more rarely-occurring strongly diffuse basophile increase of the anterior pituitary, as a primary pathological process. However, Kraus as well as Berblinger and Rutishauser, hold that there is no doubt that there is a connection between the basophile elements of the pituitary gland and bone decomposition. In favor of this fact, he calls attention to the increase of the basophile cells at a higher age, which likewise inclines towards osteoporotic altrations, and the observation of a high degree, an unusual increase of the basophile cells of the pituitary gland in severe osteoporosis. According to Rutishauser, in those cases in which osteoporosis had been developed in a high degree, an unusual increase of the basophile cells of the pituitary body could be expected.

We regret that in most of the reports of autopsies in cases of a high degree of osteoporosis there are no observations recorded regarding the pituitary gland, *e.g.* in the case of Imhauser. We can understand that Berblinger, in an observation of a woman, aged 78, affected with Cushing's syndrome, first looked upon the porotic changes as senile ones. According to Berblinger, in this syndrome are to be found "no pronounced development of osteoclasts with lacunar resorption of the bone, but thin trabeculae of spongiosa with wide spaces filled with marrow and a reduction of the corticalis from the side of the medullary cavity." Schmorl and Junghanns in cases of osteoporosis found merely a reduction of the single trabeculae of the spongiosa as well as the bone end-plates and slight reduction in the number of trabeculae. The X-ray pictures in Cushing's syndrome and in senile osteoporosis are similar. In both the cases an increased permeability of the bones to rays is noted, the finer structure being absent. Where the latter can still be seen, the trabeculae are thin and scarce. Infractions and transverse fractures can be observed in both the pictures. The interpretation of the finer hormonal processes, originating the osteoporosis in Cushing's affection, presents great difficulties. Jamin believes in a secondary influence from the parathyroid gland. Berblinger also thinks that the effect of the parathyrotropic hormone upon the pituitary gland is credible. He also thinks it possible that there is a "Wirkstoff," produced by the basophile cells of the pituitary gland, contrary in its effect to the growth hormone of the eosinophile cells. Some very interesting observations have been made by Collip and his co-workers. He has shown that, in the case of a production of growth hormone, antihormones also are found in the anterior lobe of the pituitary. This has led him to postulate the phenomenon of "inverse responsiveness," *i.e.* balance between hormone and antihormone. The basophilia of the anterior pituitary may be due to a disturbance of this balance. Perhaps this antihormone represents the supposed parathyroid hormone. We must take into consideration these lines of thought, if we intend to consider senile osteoporosis as an effect of the increase of the basophile elements of the anterior pituitary.

Kraus thinks that basophilia by itself is not sufficient to call forth changes in the bones. But just as the basophilia plays an essential part in the pathogenesis of hypertension and in Cushing's disease, so the increase of these elements is of decisive importance for the development of senile osteoporosis. Senile osteoporosis is consequently due to an abnormal behaviour of the pituitary gland in consequence of the absence of the controlling effect of the generative glands, being in a state of involution. In future, investigations will have to deal with the question of whether (1) senile osteoporosis is merely due in part to a changed hypophyseal function and must be assumed to be partly the consequence of a correlatively influenced functional change of the other endocrine organs, or (2) senile osteoporosis may also occur without those hypophyseal changes.

Recently, it has been stated, that in adults of more advanced age, osteoporosis can also develop(it being due to an insufficient administration or utilization of vitamins A or D. People are inclined to take into consideration, in explaining the origin of all sorts of bone diseases, lack of vitamin A or D. Thus the regional prevalence of hyperparathyroidism in the great industrial districts is ascribed to the short duration of sunshine and the limited securing of vitamin D, as a consequence. Thannhauser refuses to acknowledge the malacic diseases, hunger and senile osteoporosis as a nosological unity, in spite of the conformity of their histological pictures. It is not possible to consider these osteoporotic bone diseases as similar in origin to infantile rickets. The senile osteoporosis is classed with diseases due to the withdrawal of calcium and phosphate. But important relations, existing between lack of vitamin E and basophilia of the anterior pituitary, have helped in clarifying of the pathogenesis of hunger osteoporosis (Lyon).

If one desires to exert a therapeutic influence upon senile osteoporosis, he is forced to intervene in the ring of hormonal correlations and to equalize disturbances. The anterior lobe of the pituitary gland is known to be a glandular organ highly sensitive to radium and answering promptly to irradiation. By roentgen irradiation of the pituitary gland the osteoporosis in Cushing's syndrome has also been essentially improved (Jamin). Roentgen irradiation in senile osteoporosis has already been recommended formerly (Schlesinger). It is especially in cases of senile osteoporosis accompanied by obesity, at the climacterium, in which an improvement can be expected. In mild cases and for after-treatment, the administration of vitamin E may be tried; it causes no secondary manifestations, even in prolonged administration and in high dosage. Certainly, however, an essential for the beneficial effect of vitamin E is that the involution of the generative glands has not gone too far (Guggisberg).

SUMMARY

Senile osteoporosis is due to the increase of the basophile cells of the anterior pituitary, as a result of the controlling influence of the generative glands being in a state of involution

As a therapeutic measure, roentgen irradiation of the pituitary gland and, in mild cases, vitamin E are recommended.

Editorial

NEW KNOWLEDGE ABOUT THE FUNCTIONS OF THE SMALL BOWEL

IT is a remarkable fact and a sad one that the gastro-enterologist who struggles every day with the problems of indigestion knows practically nothing about the digestive and absorptive functions of the main organ of digestion, the small bowel. What is worse, he doesn't even realize, unless he stops to think, that it is the organ of digestion. All his training in college was given him with the thought that it is the stomach that he has to worry about and treat.

So strong is the hold of this assumption on scientific men that sometime ago, when physiologists and pharmacologists began to study the mechanism of vomiting, years had to pass before it occurred to anyone to think of what might be happening in the small bowel during the act. Similarly, even today, when a drug house prepares a medicine which is somewhat upsetting to digestion, the custom is to put it into keratin coated capsules so that it can be carried untouched through the stomach and out into the small bowel. This is done with the naive assumption that the stomach is the only digestive organ that needs to be considered. Actually every bit of physiologic evidence we have indicates that the stomach is far more resistant to irritants than is the small bowel, and much experimenting on animals and man indicates that nausea and vomiting can be induced more easily by irritation of the duodenum and upper part of the jejunum than by irritation of the stomach. The physiologist tells us moreover that one of the main functions of the stomach, for which it was specially designed, is to hold back and dilute and neutralize and feed slowly into the bowel irritant foods or substances which might, in strong concentration, injure the highly sensitive mucosa of the small bowel.

No, gastro-enterologists must gradually come to see and to realize at all times that the real organ of digestion is the small bowel. There is practically no absorption of food or water or even crystalloids from the stomach. In addition to holding back solid and irritating substances, warming them to body temperature, and softening and partly digesting them, it feeds the chyme gradually and as needed into the bowel. It is the small bowel that does the final digesting and all of the absorbing.

There is no doubt but that much of the dissatisfaction that any thoughtful gastro-enterologist must feel with his work today is due largely to his almost complete ignorance of the functions of the small bowel. What is more, with patients it is almost impossible for him to learn much of what is going on in this part of the digestive tract. He can pass a tube into the stomach to remove contents for analysis, and he can study the inside of this organ with the roentgen rays or with the new flexible gastroscope. Similarly, he can look into the inside of the colon and study the folds of the mucosa with the double contrast barium meal or with the sigmoidoscope. But, as yet, he cannot learn much about the central portion of the small bowel. All he can do is to get some idea of the normality or abnormality of peristalsis and of mucosal patterns at its two ends; in the duodenum and first portion of the jejunum and in the last segment of the ileum.

It is doubtless because of this handicap that in four out of five cases of diarrhea the physician is unable to find a definite cause. Seeing that in all of these puzzling cases the mucosa of the colon appears to be perfectly normal, the probability is, I think, that the disturbance of function is in the small bowel where we cannot as yet get at it very well.

Until last year anyone who turned to the literature for information as to the laws underlying the absorptive processes of the small bowel would have found very little, and that little scattered through highly technical journals. Today at last we can turn to one well-written monograph, a monument to the industry and ability of Fritz Verzár of Basel. To him should go thanks and appreciation from all of us, physiologists and clinicians, who are interested in digestion. The book should be in the library of every man who practices gastro-enterology, and it should be read and reread. For years Verzár and his pupils have been studying the intestinal mucosa and the ways in which it absorbs and digests, and here we have a good résumé of their findings, together with a fine review of the literature. I hope in a later issue of this Journal to give some idea of the riches that are to be found within the covers of this little volume.

Other excellent work has been done in this country by Wells, Cori and others, using animals, and now Grier Miller, Osler Abbott, Karr and others in Philadelphia are studying the motor and secretory and absorptive functions of the small bowel in man with the help of special tubes which are passed through the mouth far down into the small bowel. These studies are most promising, and should some day give the practicing physician some hint as to what is going wrong in the bowel of his patients with now puzzling syndromes. Finally, when we have some idea of what is going wrong, we will have some chance of doing something that will restore conditions to normal.

Walter C. Alvarez, Rochester, Minn.

Book Reviews

Traitement Chirurgical Du Cancer Du Colon Pelvien. By Pierre Bertrand and E. Corajod. Masson et Cie., Paris.

PROFESSOR Louis Tixier whose operation for cancer of the pelvic colon is well-known and described in the text, states in a preface that, nowadays, with rapidly improving technique, the mortality is on the decrease and one may often count on a definite, radical cure. His pessimism with regard to surgical cure of gastric cancer is in contrast to his hopefulness when the disease is situated in the rectum or colon. The report itself concerns an intimate follow up of 155 cases. Constipation and (or) diarrhea are the chief early symptoms, along with pain in the lower left quadrant and vague indigestion leading to suspicion of gastric trouble. Then follow symptoms associated with gradual stenosis—with bloody and mucoid stools, pain, irritable bladder. The evolution is very slow—occlusion, suppuration, fistula formation, perforation, general metastases. Precise location of the obstruction by X-ray studies is essential: a preliminary film without barium is frequently of value in showing colonic distention with gas. The barium meal ought not to be used after obstruction is complete. The opaque enema is the method of choice, and the study of mucosal relief patterns has proved helpful. Treatment is essentially that of radical removal with reestablishment of continuity of the gut. Variations depend upon exteriorization in contrast to intra-abdominal operation; and also the formation of an artificial anus. Hartmann's operation is intra-abdominal colectomy with anus formation. Tixier's operation in three stages is fully described. Encouraging results are tabulated from a prolonged follow up of cases. A note of warning is given with regard to the possibility of luetic lesions of the sigmoid resembling cancer.

The Little Things in Life; the Vitamins, Hormones, and Other Minute Essentials for Health. By Barnett Sure, Ph.D., Professor of Agricultural Chemistry in the University of Arkansas. 340 pages; published 1937 by D. Appleton-Century Company, New York. Price $2.50.

THE object of this book is to bring to the attention of the layman present day scientific knowledge regarding vitamins, inorganic salts and hormones. The author is on familiar ground when he deals with vitamins, particularly the "B" group, but when he discusses the ductless glands and their relation to nutrition he shows less familiarity with the subject. This book contains less discussion of rats and guinea pigs, and more of the application of the value of accessory food substances to human nutrition than most books on the same subject for laymen. As would be expected the two chapters dealing with vitamins in infant nutrition and during pregnancy and lactation are the best in the book.

The Little Things in Life are the vitamins, mineral elements and ductless glands. These have been discussed by the author in a sound, sane manner. This book can be recommended to your intelligent patients. The gastro-enterologist could afford to read Barnett Sure's book to get the view point of such an experienced biochemist in the field of deficiency diseases.

Lloyd Arnold, Chicago.

FALSI, ERNEST CALROLL.

The Use of Anthelmintics. J. A. M. A., Vol. 108, p. 256, Jan. 30, 1937

The anthelmintic drugs are those used to remove parasitic worms from the body of the host. In human infections the ones used are primarily drugs and dyes which act to narcotize, kill, and at times digest the worms. An ideal one is lethal to the parasite well within the limit of tolerance of the patient. Before using an anthelmintic it is well to know the species of parasite involved, the location and number in the body, the actual or potential damage produced by the parasite, the dosage of the indicated drug in adults and children, and the method of determining the efficacy of the anthelmintic following its administration.

Betanaphthol, thymol, oil of chenopodium, carbon tetrachloride, tetrachlorethylene, santonin, hexylresorcinol, ficin, and gentian violet are the most important chemotherapeutics useful in removing intestinal nematodes. Tetrachlorethylene is probably the safest efficient drug for hookworm infection, and hexylresorcinol for ascariasis and seatworm infection. Gentian violet is specific for strongyloidosis infection. Ficin is probably the best for trichocephalis infection, but is not yet available to the profession. Oil of chenopodium is very toxic and is contraindicated in many cases, although it is very potent for both hookworm and ascariasis. Carbon tetrachloride also is very toxic, but also is very effective in the treatment of hookworm and tapeworm infection.

Oleoresin of aspidium and pelletierine tannate are both very toxic, but are used in removing tapeworm. Antimony and potassium tartrate is the drug of choice in blood fluke infection. Emetine hydrochloride has not been found to be of much value except in fascioliasis. Creeping eruption is best treated by the local application of ethyl chloride.

Francis D. Murphy, Milwaukee.

Keto-cholanic Acids in the Medical Management of Low Grade Gall Bladder Disease. J. A. M. A., Vol. 108, pp. 453-461, Feb. 6, 1937.

Gall bladder disease is a well recognized cause of upper abdominal distress. The therapy of this condition is highly controversial. Some men believe that the only therapeutic measure is removal, while others believe that removal is indicated only when stones are present. The accepted medical management at the present time consists of a low fat diet, duodenal drainage, cathartics and biliary antiseptics.

The etiology of gall bladder disease

How PABLUM Compares

with five principal foodstuffs in essential minerals, vitamins and other nutritional values

Pablum consists of wheatmeal, cornmeal, wheat embryo, brewers' yeast, alfalfa leaf, beef bone, iron salt, and sodium chloride. Supplies vitamins B and G and calcium, phosphorus, iron, copper, and other minerals. Samples are available to physicians.

CONSTITUENT	PABLUM	ROLLED OATS	FARINA	WHITE BREAD	WHOLE MILK	EGGS
	%	%	%	%	%	%
Calcium	0.780	0.069	0.021	0.027	0.120	0.067
Iron	0.03	0.0038	0.0008	0.0009	0.00024	0.003
Phosphorus	0.620	0.392	0.125	0.093	0.093	0.180
Copper	0.0013	0.0005	0.00017	0.00034	0.000015	0.00023
Vitamin B (B_1)	+ + +	+ +	— to +	+	+ +	+ to + +
Vitamin G	+ + +	+	— to +	+	+ + +	+ + +
Moisture	7.0	8.0	10.9	35.3	87.0	73.7
Protein	15.0	15.2	11.0	9.2	3.3	13.4
Fat	3.0	7.3	1.4	1.3	4.0	10.5
Carbohydrate	70.8	66.2	76.3	53.1	5.0	—
Calories per oz.	106	110	103	74	20	42
Alkaline Reaction	V				V	

Pablum is rich in minerals and vitamins. It is noteworthy that the calcium - phosphorus ratio of Pablum is 1.2:1, similar to that of average whole milk, which is considered the most favorable ratio for retention.

These figures are included to illustrate ordinary nutritional values. Calories, carbohydrates, fats, and proteins no longer constitute a serious nutritional problem.

†PABLUM (Mead's Cereal, thoroughly cooked) contains nine minerals (principally calcium phosphorus, iron, and copper) and vitamins B and G in substantial amounts—in addition to abundance of protein, fat, carbohydrate and calories. Pablum is palatable and requires no further cooking. Supplied in 1 lb. packages.

should be used if pus or other secretions are present. If erosions are present they should be irrigated with weak silver solutions. Milk should be avoided in the atrophic form. Hydrochloric acid may relieve some of the distress. Parenteral liver should be tried in all atrophic forms.

Francis D. Murphy, Milwaukee.

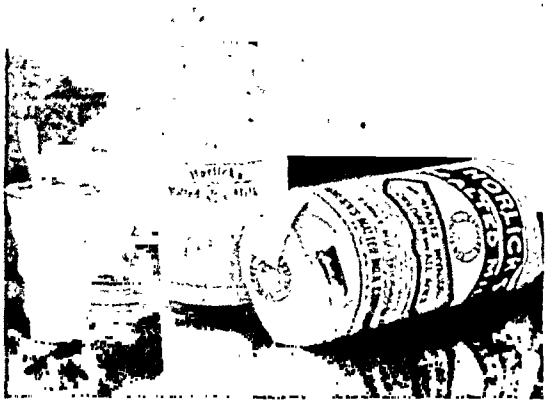
STUCK, I. E., DEUTSCH, H., REED, C. I. AND STRUCK, H. C.

"Further Studies on Intoxication with Vitamin D." Ann. Int. Med., X, 951, Jan., 1937.

The work reported by these authors on Vitamin D was built around the following hypotheses.

(1) Proper vitaminosis D may produce symptoms of hyperparathyroidism.

(2) The therapeutic use of Vitamin D is rational only in conditions of known deficiency.



(3) Animals experimentally treated with Vitamin D concentrates have shown extensive calcium deposits in various tissues and other pathological changes have been found.

Their work covered observations on dogs, supplemented by studies on human beings.

In their experimental work on dogs they found that the changes which occurred as the result of the toxic effects of Vitamin D consisted of a cellular injury which took precedence in occurrence and that this was followed by calcium deposition at the site of the cellular injury. Extensive damage to renal structures was noted, while medial thickening in arteries was observed in but four of the 64 dogs studied. Loss of weight was a rather common result and this they thought was due to impoverishment of fat depots. Premortal coma was described as one of the characteristic features of fatal hypervitaminosis D. This condition was usually preceded by partial paralysis, slow shallow respiration, fine, thready, rapid pulse, salivation and frequently by psychic changes of such nature that a previously friendly dog would become unmanageable or even vicious. The objective symptoms of toxicity noted are listed as weakness and lassitude, anorexia, polydipsia, polyuria, diarrhea and psychic disturbances. The bloody feces observed was explained on the basis of petechial hemorrhages found in both the stomach and the intestines at autopsy.

As a matter of dosage they noted that dogs received 20,000 units or less per kilogram of body weight showed no evidences of cell injury and only an insignificant weight loss, with very little toxic manifestations. The observations on these dosages covered a period up to 153 days. Attention is invited to the fact that diet is a very important factor in conditioning toxicity of animals. They feel that there is no causal relationship between what is termed hypercalcemia and toxicity, and object to the use of these terms interchangeably by authors.

In their observations on human subjects attention is invited to what appears to be enormous doses of Vitamin D that have been administered to human beings, but they claim that when consideration is given to the weight-dosage relationship that few of the human subjects reported have ever received doses comparable to the large doses tolerated by their dogs in their series of observation. The routine dose which they gave to human beings ranged up to 200,000 units daily for periods covering from seven days to two years. This represents approximately 4,000 units per kilogram per day. The shortest period of administration that resulted in intoxication in their group of human beings ran from 3 to 5,000 units per kilogram per day was 87 days. In the group that were on a dosage of from 6 to 7,000 units per kilogram per day the shortest period for development of toxicity was

FOR YOUR NEXT ULCER CASE—

Horlick's Malted Milk offers a bland and soothing diet for peptic ulcer patients. This partially predigested food is well balanced in nutriments, is simply prepared and is delicious but not cloying to the taste.

Horlick's when used with either milk or water is slightly alkaline, has a soothing, protective effect on delicate mucous membrane, yet is high in nutritional value.

Horlick's Tablets are especially convenient for "in between meal" use. A small flask may be carried, or kept at hand, offering suitable nourishment at required intervals.

Horlick's Malted Milk Corporation
Racine, Wisconsin

Bisiodide

IN THE ORAL TREATMENT OF SYPHILIS

Bisiodide is a complex organic compound of bismuth and iodine which on oral administration is absorbed and produces a high and constant concentration of bismuth and iodine in the brain, spinal cord and other tissues.

Used concurrently with arsenicals in primary and secondary stages and independently in tertiary stages, *Bisiodide* produces clinical improvement and serological reversal, frequently where other remedies have been unsuccessful.

SALB LABORATORIES, INC.
34 UNION TRUST BLDG. INDIANAPOLIS, IND.

66 days. The symptoms that they list as characteristic of hypervitaminosis D in human subjects are dependent first upon cellular degeneration that occurs most commonly in the kidney, with a concurrent loss of weight, and second, to a deposition of calcium which occurs at the site of all cell injury, and third, up to advanced stages of toxocity they concluded that these processes were reparable if Vitamin D administration be discontinued. Calcium appears to be excreted by the urine when removed from tissues during recovery, and it may be concluded that repair is not complete in any patient until the urine calcium excretion becomes normal. The source of the initial increase in calcium in the urine has not been definitely determined, but it is thought to come from the trabeculae of the bones. Concerning the factor of age they state that older subjects are usually less readily intoxicated, but recover less readily when intoxication does occur than in the younger persons. They have found on record only two instances of death in human subjects certainly due to hypervitaminosis D. As a contraindication to the use of Vitamin D they suggest that kidney dysfunction should constitute an absolute contraindication, for the present, at least. They also believe that hyperthyroidism accentuates the tendency toward pathological effect.

The article concludes with the following summary and conclusions:

1. Observations on 61 dogs and 773 human subjects receiving massive doses of Vitamin D have been made and data recorded as to the dose per unit of body weight and on the nature of the process of intoxication.

2. Both human subjects and dogs generally survive the administration of 20,000 units per kilogram per day for indefinite periods without intoxication.

3. Hypervitaminosis D first produces cell injury followed by calcium deposition. This process is reversible and reparable if administration is discontinued promptly.

4. Intoxication for short periods does not result in any permanent injury that can be recognized by the methods employed in this investigation.

Virgil E. Simpson, Louisville.

GRAHAM, ROSCOE R.

Diverticulitis of the Sigmoid Colon. Can. Med. Asso. Jour., 36:1, 1-7, Jan., 1937.

Many cases of colon disturbance are labeled and treated as "colitis" without proper examination and study. Most of such cases are functional but occasionally there is an organic lesion responsible, especially carcinoma or diverticulitis. The reason for seeking relief is one or both of the following reasons: a change in the rate of flow of the content (diarrhea or constipation) or a change in character of the content (increase or decrease of fluid, presence of blood, mucus, or pus).

Diverticulosis which must precede diverticulitis, is present without symptoms in about 5% of persons subjected to X-ray examination of the colon for any cause. Diverticulitis develops in approximately 12% to 15% of cases of diverticulosis. The frequency of diverticulosis is about 12 in a thousand; that of diverticulitis is one in a thousand. Diverticulitis rarely occurs under 35 years of age. This study of 41 cases covers a group which had progressed to a point requiring surgical consultation.

Acute diverticulitis is divided into *simple, non perforating, and perforated.* Chronic diverticulitis is divided into *non-perforating with adhesions and obstruction and slowly perforating with abscess about the sigmoid, in the mesentery, or into adjacent viscera.* Twenty-five per cent of the patients in this study underwent emergency operation for acute perforation. Diagnosis in the acute group is difficult. No mass

When Economy is a Consideration

Home-prepared strained foods are not usually economical. They are often *minus* considerable percentages of vitamins and minerals because most mothers cook them so that they are accessible to oxygen; further, part or all the moisture is poured off. The doctor who recommends Gerber's Strained Foods recommends a product which retains to a high degree important vitamins and minerals; a product in which there is no waste; which is always uniform, truly economical; which relieves the busy mother of a strenuous, unprofitable daily task.

No mother can strain and cook as we do. In Gerber's kitchens only the finest are selected from *Home Grown* pedigreed vegetables, grown on farms within an hour's trucking distance. All cooking and straining are steam pressure in closed systems, with temperatures constantly controlled, for greater prevention of oxidation and to prevent reduction in vitamin potency—and with vacuum evaporation of excess moisture to conserve minerals.

"DOCTOR, HE JUST WON'T EAT"

A Special Food Supplement Added to the Child's Diet

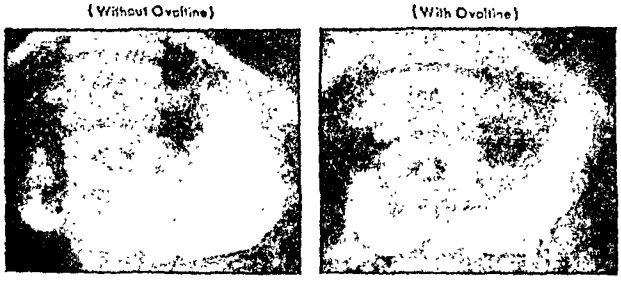
Frequently Improves Appetite and Helps to Correct Underweight

OVALTINE is the food supplement which many doctors are recommending to help restore appetite and add weight. It contributes to weight gains in several ways—

First—Ovaltine helps to restore normal appetite. It tempts the taste and in addition, it helps to stimulate the lagging appetite. It contains 57 International units per ounce of the appetite-restoring vitamin B. It also makes possible the prompt return of hunger by causing the stomach to empty starchy foods more rapidly. (See x-rays below).

Second—Ovaltine possesses other special properties which are also important when digestion is under par. It not only aids the digestion of starchy foods, but it increases the digestibility of milk. Furthermore, Ovaltine itself is very easy to digest.

Third—Ovaltine adds important growth factors to the diet. It contains complete proteins, easily available carbohydrates, vitamins A, B_1, B_2 (G), and D, and the minerals calcium, phosphorus and iron.



Developed in Switzerland over 40 years ago as a food for convalescence, Ovaltine has stood the test of time. It makes an ideal food for underweight children because it combines both nourishing and protective food elements in an attractive form. Recommend the use of Ovaltine for underweight children and see for yourself the results it can bring.

Let us send you a regular size can of Ovaltine for clinical trial with some undernourished child under your care. Address The Wander Company, 360 North Michigan Avenue, Chicago, Illinois.

Dept. D.N. 7

(Without Ovaltine) (With Ovaltine)

The two x-ray reproductions show the stomach two hours after a starch meal was taken, with and without Ovaltine. The average decrease in gastric contents due to Ovaltine was 20%.

was palpable in the acute cases. "Pain in the lower abdomen—radiating to the rectum and temporarily relieved by the passage of flatus or stool, is a very significant symptom." The results from general treatment with intravenous fluids, heat locally, and sedation are justified even though operation is delayed several hours. Operation consists of exposure of the perforation, the placing of a rubber tube to the site, and walling off the surrounding area with gauze saturated with liquid paraffin containing BIPP. In obstruction requiring decompression a cecostomy is preferred to a colostomy because it is *simple, effective, easy to close*, and it acts as a safety valve if resection is necessary. Cecostomy is done by attaching the bowel to the skin by interrupted sutures.

Most cases of chronic diverticulitis are characterized by "recurring vague abdominal distress with definite periods of acute illness" in patients over 40 years of age. Symptoms commonly consist of constipation, fever, and acute pain. Less often there is bleeding, tenesmus, obstruction, lower abdominal mass or a tender mass palpable rectally. X-ray is of distinct help in many but not all cases. The cases treated were practically all surgical and therefore an opinion concerning early treatment is of no value. Based on the few nonsurgical cases, however, treatment would include prolonged bed rest and dietetic control with periodic examination over a year or two provided *response is satisfactory*. Resection in the cases not responding to the above treatment would save invalidism, economic loss of time, and the possibility of erroneous diagnosis especially in carcinoma of which there were seven cases in this group.

The presence of a mass is not an indication for emergency treatment. Nor should a patient with a left colon mass be diagnosed carcinoma until diverticulitis has been excluded etiologically. There were 13 diagnostic errors in this group of 44. Five cases diagnosed diverticulitis proved to be carcinoma. Differentiation of inflammatory and neoplastic lesions of the colon may be very difficult or impossible or the two may coexist.

Wayne W. Flora, Chicago.

KANTOR, J. L. AND COOPER, L. F.

"Dietetic Treatment of Constipation with Special Reference to Food Fiber." Ann. Int. Med., X, 965, Jan., 1937.

The authors pay their respects to the domination in medical literature of advertised artificial bulk producers in the treatment of constipation during recent years. Listed among these bulk producers is mineral oil, agar, bassorin, psyllium seed, cellulose and bran, and they call attention to the fact that these substances cannot be employed indefinitely without the possibility of interference with nutrition. They then make a plea for a refocusing of attention on diet by the medical profession in the treatment of constipation. Acknowledging the work of Rose and Cowgill and their associates, the authors stress the fundamental physiological fact of the quantitative relation between the amount of crude fiber ingested and the resultant laxative effect. They accept a daily intake of from 90 to 100 mgms. of fiber per kilogram of body weight as being sufficient for an adequate laxation. Attention is also invited to the dearth of helpful data to be found in American books on diet. For even approximate estimations of the quantitative employment of diet in the treatment of constipation the reader must go back as far as 1921, when von Noorden wrote concerning his advocacy of the use of a bulky diet for constipation. In their list of research work the authors confine their observations to fruits and

tirely, and of this group of foods to only three representatives, prunes, apples and bananas. They found the fiber content of prunes to be 1.9 per cent, of apples 1.4 per cent and bananas 0.6 per cent respectively.

Their experimental work appears to have been well controlled and consisted of a preliminary period when the subjects on whom the observations were made were allowed what they desired. The diet on which they were subsisting was submitted to a determination of fiber content, the weight of the patient was kept and the individual laxative frequency recorded. As a result of their experimental work it was found that prunes had a laxation effect of 7.7 and a colon emptying time of 91 hours. Bananas had a laxation effect of 6.8 and a colon emptying time of 98 hours, while apples had a laxation effect of 6.1 and a colon emptying time of 115 hours. Calling attention to the fact, however, that the number of stools was not an accurate guide to the laxative effect, the following additional criteria was set up. Prunes gave the best laxative effect in five subjects, apples in three and bananas in one. Considerable variation in the personal preference on the part of the experimental subject was noted. The most constipated individual in the group rated apples first, bananas second and prunes last. This rating was made on a basis of subjective impression.

In discussing the clinical applications of some studies on diet for the relief of constipation the standard of Cowgill of 100 mgms. of fiber per kilogram of body weight was accepted, and then they insisted that in planning a diet for a constipated person the same precision with regard to the fiber content should be observed as one would exercise in prescribing a diet for diabetes or obesity. Tables were given listing foods showing the fiber content. Their observations led to the conclusion that the addition of fruits to the diet of a constipated person in the amount of 33 mgms. of fiber per kilogram of body weight added to an average diet containing approximately 66 mgms. per kilogram of fiber from other sources should relieve constipation in most of the simpler cases.

The authors give the following summary of their work.

1. An adequate fiber intake is important in the dietetic treatment of constipation. Fiber is supplied by three classes of foodstuffs—fruits, vegetables and cereals.

2. The relative laxative value of typical fruits was studied in human subjects on a fiber-equivalent basis. Previous work showing that the laxative effect of a diet depends largely on its fiber content was confirmed and the value of such typical fruits was demonstrated. Although prunes were found to be generally more laxative than apples or bananas, yet each of the latter proved more effective in individual cases. There is reason to believe that bananas are of special value in constipation associated with colonic instability.

3. Tables are furnished showing the fiber content of the common fruits, vegetables and cereals, in per cent by weight and in amount per portion.

4. In the selection of fibrous foods only bland articles should be used at the beginning of treatment because rough foodstuffs may provoke bowel irritation with resulting spasm and increase in constipation.

5. For the relief of many if not most cases of simple constipation ordinary servings of fruit should be taken three times daily, preferably as desserts. The daily use of approximately 2 grams of fruit fiber in addition to the average diet containing four vegetables

Prompt Relief from Pain
Quicker Healing of Mucous Membranes

KAO-MUCIN with ALLANTOIN

COMPLEMENTARY THERAPY

HYCOLA ... HYCOLA assists the therapeutic action of KAO-MUCIN with ALLANTOIN ...

THE ADVANCED
Therapy in Peptic and Duodenal Ulcers

This remarkable combination of KAO-MUCIN C. P. Co. (concentrated okra) with ALLANTOIN (the famous development from maggot therapy) is securing almost miraculous results for gastroenterologists in the treatment of peptic and duodenal ulcers.

THE REASON—

KAO-MUCIN in the presence of dilute hydrochloric acid forms a gel, or coating, which spreads itself over the stomach mucosa and has a soothing, protective effect resulting in prompt relief from pain. ALLANTOIN, the powerful cell proliferant, promotes the growth of new mucous tissue over the ulcerated and congested surfaces and promotes more rapid healing.

Supplied in packages of 100 tablets. Samples gladly furnished upon request.

(4th of a SERIES)

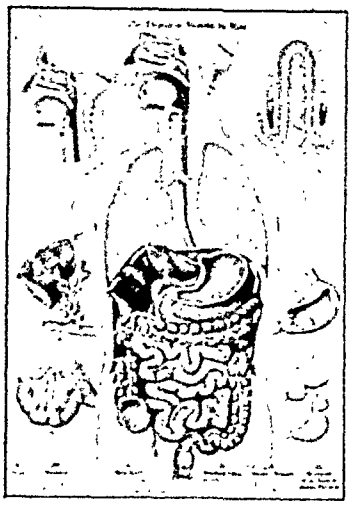
Salines

in CUMULATIVE CONSTIPATION

Although they may have a movement daily, sedentary individuals who eat excessively are benefited by taking salines once a week or at other regular intervals. This eliminates the redundant feces accumulated during the week.

Sal Hepatica

is doubly beneficial in cumulative constipation: it helps to rid the intestines of excess waste, gently, surely and thoroughly. Mild stimulation of the intestinal musculature, diminished absorption and increased osmosis accomplish this end. Sal Hepatica also supplies physiologic mineral salts to replenish the alkaline store. The system is better able to ward off disease; general well-being is improved. Sal Hepatica stimulates an increased rate of bile flow from the liver into the gall bladder and thence, into the duodenum.



Sal Hepatica efficiency closely resembles that of famous natural aperient Springs. It makes a fine, effervescent drink . . . Samples and literature upon request.

JUDIN, S. S.

Partial Gastrectomy in Acute Perforated Peptic Ulcer. Observation on Diagnosis and Treatment of 426 New Cases. S. G. O., Vol. 64, No. 1, pp. 63-68.

The authors present in detail a case of pancreatic fistula which developed in an 18 year old male who was kicked in the abdomen while playing football. On the day following the accident the patient complained of abdominal pain with nausea and vomiting; his abdomen was explored and a drain inserted into a hemorrhagic area in the gastrocolic omentum. The amount of fluid which drained from the pancreas varied from 532 to 663 cubic centimeters daily. The quantity varied with dietary regulations and alkaline medication. The physical and most of the chemical characteristics of the fluid are given in the article.

After a period of time during which conservative measures were tried and failed to stop the drainage from the fistula, operation was decided upon. The fistula was excised from the abdominal wall and inserted into the jejunum. Recovery was uneventful.

A review of the literature, five figures, and bibliography accompany the article.

N. M. Percy, Chicago.

LAHEY, F. H. AND LINN, R.

Cure of Pancreatic Fistula by Pancreato-jejunostomy. S. G. O., Vol. 64, No. 1, pp. 79-88, Jan., 1937.

The author describes an oblique upper right rectus muscle splitting type of incision for the suture of acute perforations of peptic ulcer. Its advantages are that it is short, easy to make, little bleeding is encountered, little packing off is required, and the liver edge helps prevent herniation of the viscera if the wound separates. This wound may be extended to permit operative procedures on the gall bladder and may be closed readily if a low abdominal incision must be made.

Five figures accompanying the article show the technique in detail.

N. M. Percy, Chicago.

Calcium Requirements in Man. Edit. Brit. M. J., p. 869, April 24, 1937.

In reviewing and commenting upon a recent survey of the calcium requirements of man by Dr. I. Leitch, the *Journal* points out that this authority calculates the daily maintenance requirement of adults at 0.55 gram, whereas Sherman has put it at 0.45. Many diets in America and England do not, however, reach even this lower figure of calcium intake. During adolescence, the need for calcium is especially high, increasing up to 2 grams daily between the ages of 15 and 16 years. Assuming that milk provides two-thirds of the calcium, children of this age need two pints of milk a day.

There is evidence to show that breast milk is often qualitatively and quantitatively inadequate as a source of calcium for the infant. To maintain the optimum of 10 grams of this mineral per kilogram of body weight, the intake must be 0.2 gram at one month and 0.52 gram at 6 months, but many nursing mothers do not provide this amount. Although cow's milk contains nearly four times as much calcium as breast milk, its buffering power is greater, but this can be reduced by treating the milk with acid. One of the functions of vitamin D seems also to be to lower the pH of the intestinal contents and hence increase the absorption of calcium. There is, however, a paucity of knowledge of the processes of absorption from the intestine. Another urgent need is to ascertain whether the calcium content of breast milk can be affected by the mother's diet.

Calcium Therapy in Dentistry. Edit. J. Am. Med. Ass'n., 108:1655, May 8, 1937.

Conclusions of the Council on Dental Therapeutics of the American Dental Association regarding the use of calcium in human nutrition and in the control of dental caries are summarized as follows:—

1. All the calcium and phosphorus requirements for average needs, including pregnancy and growth, may be suitably obtained by means of an adequate diet containing not only calcium and phosphorus compounds but also other necessary factors, such as caloric, protein and other mineral and vitamin requirements.

2. There is no carefully controlled evidence that the addition of calcium and phosphorus compounds, whether inorganic or organic, promote retention of these elements and hence freedom from dental diseases, except in known cases of deficiency. Where this occurs, milk serves as an excellent source of calcium and phosphorus in a readily assimilable form.

3. There is no evidence that the ingestion of combinations of calcium and phosphorus in addition to diets adequate in these elements promotes the development of sound teeth in the human fetus. The calcification of the teeth is a postnatal event.

Foods containing vitamin D are, however, of value in exerting a favorable influence on the absorption and subsequent deposition of calcium and phosphorus in the bones and teeth, and are an aid in the prophylaxis of dental caries.

SMITH, E. E. AND FRIED, R. I.

A Clinical Study of the Apple Diet in the Treatment of Diarrhea in Infants. J. Pediat., 10:395, April, 1937.

Although there have been many reports of successful treatment of infantile diarrhea with an apple diet, the authors were unable to find any appreciable difference in the results obtained by this means or by other types of therapy. Out of 90 cases studied, 28 were put on the apple diet, and 12 on a starvation treatment followed by protein milk. The apple diet was of no value in the treatment of dysentery, and was no better for mild and severe types of diarrhea than any other type of treatment. The care of diarrhea, the authors contend, depends on rest for the gastro-intestinal tract, parenteral fluids, supportive measures, and maintenance of the mineral balance.

BRAILEY, A. G.

Treatment of Constipation. N. E. J. M., 216:697, April 22, 1937.

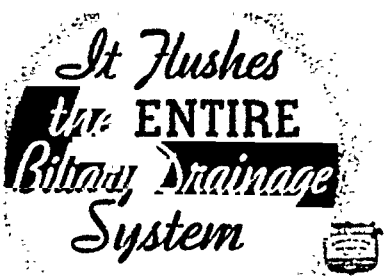
Ninety-eight of 100 consecutive private patients who gave constipation as the major complaint were cured by means of adherence to the following regular schedule:—

1. Sleep—a regular time for rising and, insofar as is practical, for going to bed.

2. Meals—no eating between meals (no unusual amount of roughage.)

3. Fluids—at least 8 full table glasses daily (milk, fruit juice, water, etc.)

4. Exercise—at least 30 minutes daily (strenuous enough for some breathlessness and palpable perspiration.)



5. Toilet visit—stay 15 minutes, if necessary, without straining; if possible, ignore calls to stool at any other time; no laxative or oil is allowed, but, if 3 days elapse without any sort of stool, take a small, warm water enema at the end of the usual toilet visit on the third day.

An interval of 3 days without a stool has seldom occurred, says the author, and more than one enema has been very rarely required.

SAFE WEANING—

The Baby Regulates Breast Feeding

An Obligation to Infants

The Doctor Regulates Bottle Feeding

INFANTS should be weaned from the breast at eight months. The season of the year is immaterial with modern knowledge of nutrition and hygiene. Gradual weaning is desirable. It is accomplished by progressively increasing the number of bottle feedings in substitution for the breast feedings.

The formula consists of 6 ounces milk, 2 ounces water, 2 teaspoons Karo for each bottle—one the first week; two the second, etc. The schedule for additional foods remains the same as during nursing. But babies unaccustomed to the bottle often refuse it as long as the breast is available. Then abrupt weaning becomes necessary, some person other than the mother giving the feedings.

The formula in abrupt weaning prepared for the entire day consists of 24 ounces milk, 8 ounces water, 3 tablespoons Karo, divided into 4 feedings, 8 ounces each, at 4 hour intervals. The formula can be concentrated once the baby is adjusted to the bottle feeding.

Karo is a mixture of dextrins, maltose and dextrose (with a small percentage of sucrose added for flavor) practically free from protein, starch and minerals. Karo is a non-allergic carbohydrate, not readily fermentable, well tolerated, readily digested, effectively utilized and economical for both the baby and the budget.

COOK COUNTY GRADUATE SCHOOL OF MEDICINE

In affiliation with COOK COUNTY HOSPITAL

Announces

Twenty Hour Course in Gastroscopy

By Professor Rudolf Schindler

The course will consist of practical work in the use of the flexible gastroscope designed by Dr. Schindler, formerly of Munich, Germany. Gastroscopic examinations will be made daily, and during the second week gastroscopies will be carried out by each student. The clinical, x-ray and gastroscopic findings will be compared.

The course will occupy two hours daily from Monday to Friday for two weeks. Courses are offered on July 5-17 and August 2-14. Minimum attendance 2—Maximum attendance 4.

From July 19th to July 31st, Dr. Aaron Arkin and Dr. Rudolf Schindler will offer a forty hour course in Gastro-Enterology and Gastroscopy.

For further information address the Registrar, 427 South Honore St., Chicago, Illinois.

brewer's yeast had from 20 to 21 units per gram, dried whole milk 5.3 units, cottonseed meal 2.9 units, and soy beans 2.1 units per gram. Although the milk came from a pellagrous region in South Carolina, it is apparently as potent in flavin as that from other localities. These results are comparable with those of other investigators, whose reports are cited and discussed.

The authors point out that flavin is a definite growth-promoting substance, is concerned in the maintenance of a normal skin condition, and plays a part in food utilization and stimulation of the appetite, but that recent investigations have indicated that flavin is not effective in the prevention or treatment of human pellagra. This disease yields, however, to another nutritional factor, apparently a part of the vitamin B complex, although not vitamin B_6. What was hitherto called vitamin G is now known to consist of at least the two factors, flavin and vitamin B_6.

PHILPOTT, N. W. AND BARRETT, C. V.

The Freezing of Human Milk as a Means of Preservation. Can. Med. Ass'n. J., 36:505, May, 1937.

Endeavors to reduce the mortality of premature babies, as undertaken by the Royal Victoria Montreal Maternity, consist primarily of: (1) meticulous cave-room care; (2) intelligent nursing and medical treatment; (3) adequate and proper feedings.

Since breast milk is essential for prematures, such milk is collected from healthy mothers, pooled and boiled, and the surplus is frozen and stored. The human milk is preserved by the quick freezing method with dry ice, and kept in a special refrigerator at a temperature of 10 degrees below zero. When needed, the milk is thawed. There is very little change in its composition, and there is a definite reduction in its bacterial content while frozen.

As a result of the various procedures used, there has been a gratifying reduction in the mortality of premature babies at this hospital.

(ED. NOTE: A reprint of a popular article in the May, 1937, issue of *Good Housekeeping*, which describes the quick freezing process for breast milk as developed at the Directory for Mother's Milk in Boston, will be sent on request.)

Further Advances in the Milk Industry. Edit. N. E. J. M., 216:802, May 6, 1937.

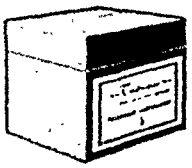
Special advantages of certified milk are outlined in this editorial, which calls attention to the fact that standards for this product are more rigid than for all other grades of milk, although practically all milks sold in Boston now exceed their standards by wide margins.

The allowable bacteria count for certified milk is only 10,000 per c.c., and when pasteurized, only 500 per c.c. All cattle are tested at least twice yearly for tuberculosis, and for the presence of *Brucella abortus*. The maximum allowable age of certified milk before pasteurization is only 24 hours, and this grade of milk must be delivered within 30 hours. It is, therefore, the freshest milk supply available.

Employees on certified milk farms are subject to medical examinations at least weekly, and cattle are examined by veterinarians at least monthly.

Pasteurization of all but a proportion of the certified milk, says this editorial, puts the final seal of safety on this important part of our food supply.

Pasteurization. Edit. N. Y. Med. Week, p. 4, May 1, 1937.



The quasi-medical article entitled "Is Milk Cancer's Ally?" in the March issue of *Current* shows so little knowledge of either milk or cancer, says this editorial, that it is very dangerous to feed. More people than should be are influenced by this sort of pseudo-scientific [illegible] are unable to evaluate the quoted results and

LARGER DOSAGE UNNECESSARY

Large doses of iron are no longer necessary for the successful treatment of hypochromic anemia. Independent investigations have proved that Hematinic Plastules yield rapid clinical response, equivalent to the results obtained from massive doses of other forms of iron • The average patient requires only three Hematinic Plastules Plain daily which obviates the unpleasant effects usually associated with massive iron feedings ◦ We will be pleased to send samples and literature on request.

THE BOVININE COMPANY • 8134 McCORMICK BLVD. • CHICAGO, ILLINOIS

CHRONIC CONSTIPATION

will respond readily to the smooth-non-irritating bulk of Testagar. TESTAGAR is a compound of husks of Plantago Loeflingii Linn combined with the finest Agar-Agar. It forms a jelly-like fecal mass in the intestine stimulating peristalsis and producing satisfactory results.

Samples will be sent for clinical test on request.

BILE SALTS
Fairchild

The sodium glycocholate and taurocholate, the salts of conjugated colic acids in their native association as separated from fresh ox gall.

A stable dry powder; uniform in composition; efficient for the well known therapeutic uses of ox-gall—in disorders due to faulty bile functioning.

Bile Salts preferably to be dispensed in capsule by itself, or in combinations in powder.

Offered in powder, ¼ oz., 1 oz. vials; in capsules, each three grains Bile Salts.

Fairchild Bros. & Foster
New York

frequently accept printed allegations that have no valid foundation.

"An article which without scientific evidence undermines public confidence in a basic food like milk," continues the editorial, "has no place in a reputable publication." The editors of this magazine, in their effort to be "advanced" have leaned so far forward that they have somersaulted to a bad fall. The intelligent reading public can have no respect for a publication which lags so far behind the scientific times as to accept uncritically an unverified theory linking cancer to milk.

(ED. NOTE: The May, 1937, issue of *Coronet* makes partial amends by printing an article by Dr. Clarence Cook Little, in which it is stated that there is no evidence to show that diet plays any part in cancer, and that milk certainly can not be incriminated in malignant growths.)

More Medical Misinformation From Consumers' Research. Edit. J. Am. Med. Ass'n., 108:1718, May 15, 1937.

An article on diet and common colds in *Consumers' Digest*, a more or less popular magazine issued by Consumers' Research, is vigorously condemned in this editorial. The alleged cold-preventing diet recommended in this unscientific journal would consist of adequate protein with a minimum of carbohydrate, using liberal portions of lean meat, poultry, fish, cheese, eggs, and other animal products, and restricting intake of potatoes, corn, beans, cereal, pastry, candy, syrup, soft drinks, ice cream, sherbet, alcoholic liquors, sweet fruits and "—of all things—fruit juices."

"Again, apparently without adequate consultation with medical authority, and this time even without adequate survey of recently available evidence," declares this editorial, "Consumers' Research presumes to dispense bad medical advice to its perhaps too trusting readers."

Is Pasteurization Harmful? Edit. Lancet, 232:1173, May 5, 1937.

Studies undertaken at the Rowett Institute on behalf of the Milk Nutrition Committee, of which Lord Astor is chairman, show that the changes in milk caused by pasteurization are of no consequence. There is no change in the nutritional availability of the calcium and phosphorus, no alteration in the biological value and true digestibility of the nitrogen, and no damage to vitamin A or its precursor, carotene. There is some loss in vitamin B_1, and about 20 per cent of the vitamin C disappears if the milk has been exposed to light before heating.

The results, says the editorial, "already show that milk suffers no damage by pasteurization that is important, compared with the risks of drinking it raw."

FRANDSEN, J. H.

Some Milk Superstitions. J. Home Econ., 29:243, April, 1937.

Various popular misconceptions concerning milk are corrected by the author, who gives scientific facts to prove that:—

a. Acid fruits and milk may be consumed together, with a resulting increase in digestibility.

b. Fish and milk are in no way incompatible.

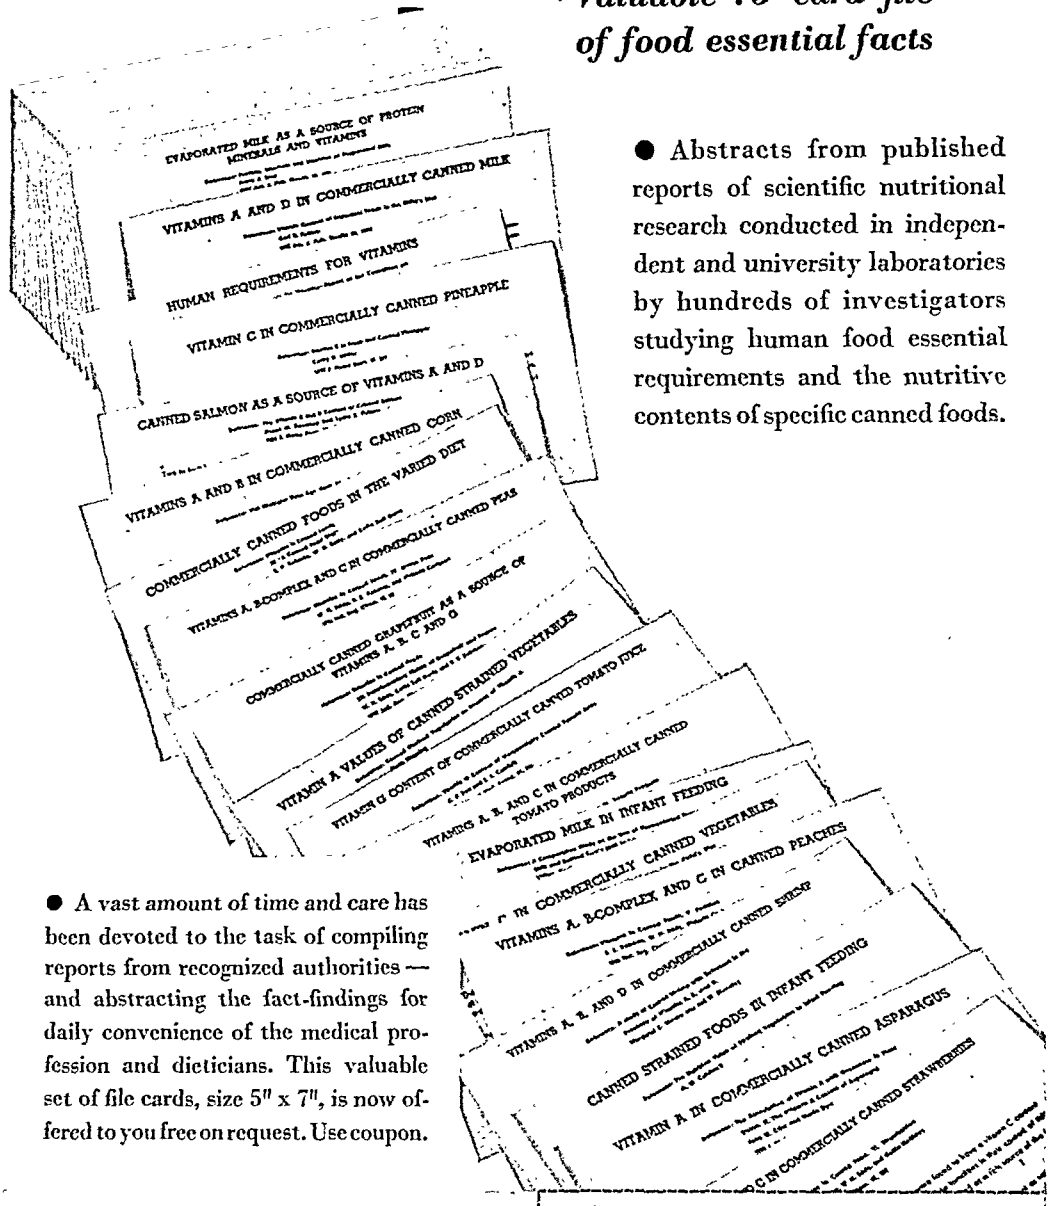
c. Milk need not be sipped, but should be drunk naturally and liberally for best curd formation in the stomach.

d. Milk is a negligible source of digestive troubles.

e. Milk is not in itself a fattening food.

f. There are no physiological reasons why milk and meat should not be eaten together.

g. Milk is not merely a food for infants but is a well balanced diet for adults.



h. Milk has more solid food than most vegetables, and its bulk is not disadvantageous.

i. Milk is not constipating in a normal balanced diet.

j. An occasional exception to these facts in diseased conditions is of incidental importance.

FOR THE PROFESSION ONLY

Valuable 75-card file of food essential facts

● Abstracts from published reports of scientific nutritional research conducted in independent and university laboratories by hundreds of investigators studying human food essential requirements and the nutritive contents of specific canned foods.

● A vast amount of time and care has been devoted to the task of compiling reports from recognized authorities — and abstracting the fact-findings for daily convenience of the medical profession and dieticians. This valuable set of file cards, size 5" x 7", is now offered to you free on request. Use coupon.

How PABLUM Compares

with five principal foodstuffs in essential minerals, vitamins and other nutritional values

Pablum consists of wheatmeal, cornmeal, wheat embryo, brewers' yeast, alfalfa leaf, beef bone, iron salt, and sodium chloride. Supplies vitamins B and G and calcium, phosphorus, iron, copper, and other minerals. Samples are available to physicians.

CONSTITUENT	PABLUM	ROLLED OATS	FARINA	WHITE BREAD	WHOLE MILK	EGGS
	%	%	%	%	%	%

Alkaline Reaction	√				√	

Pablum is rich in minerals and vitamins. It is noteworthy that the calcium - phosphorus ratio of Pablum is 1:2:1, similar to that of average whole milk, which is considered the most favorable ratio for retention.

These figures are included to illustrate ordinary nutritional values. Calories, carbohydrates, fats, and proteins no longer constitute a serious nutritional problem.

PABLUM (Mead's Cereal, thoroughly cooked) contains nine minerals (principally calcium phosphorus, iron, and copper) and vitamins B and G in substantial amounts—in addition to abundance of protein, fat, carbohydrate and calories. Pablum is palatable and requires no further cooking. Supplied in 1 lb. packages.

The Role of the Liver as the Commissariat of the Body*

By

FRANK C. MANN, M.D.†
ROCHESTER, MINNESOTA

IN pioneer days the head of the household was called the provider of the family. It was his duty to supply the fundamental necessities for sustaining life. The most important of these necessities and usually the most difficult to secure was food. It is in this sense that I wish to present the major functions and activities of the liver as the commissariat of the body. With such a view in mind, I have attempted to assemble and correlate what appear to be the more significant known facts concerning hepatic activity in maintaining the food supply to the body tissues and to present some of the major problems of metabolism as they relate to the functions of the liver. I realize that only a small part of my ambitious concept can be attained because of the many and intricate mechanisms involved, the inadequacy of exact knowledge concerning many of them, and the large amount of undigestible evidence presented on the subject. These facts in themselves are significant because they emphasize the importance of the liver and the need for future researches.

Food is a constant necessity for living protoplasm. It is needed for growth and repair of living tissues and for energy to produce the heat and mechanical activity of the living organism. The unicellular organism has the capacity to metabolize food in all important details, as digestion, absorption and utilization within itself, and such processes constitute a large portion of its activities. In the multicellular organism, a division of the activities related to food and its utilization becomes essential and cellular specialization necessarily develops. Higher organisms do not obtain their food continuously, but their tissues are constantly in need of foodstuff. To supply a constant stream of such material which can be quickly transformed into energy is the major function of the liver and the one which I wish to emphasize.

SOME GENERAL PHYSIOLOGIC REACTIONS OF THE LIVER

The liver has very many important general reactions; the most pertinent in relation to this subject is the rapidity and multiplicity of its activities. The multiplicity of hepatic activities in relation to metabolism need hardly be emphasized, as the capacity of the organ in this respect is generally accepted, even to such an extent that metabolic processes which cannot be proved to occur in any given tissue are not infrequently thought to take place in the liver, although there may be no evidence for such an assumption. The rapidity with which the liver functions in many metabolic processes is not so well known, and failure to realize this fact may be one of the important reasons for some of the contradictory data and conflicting views on liver function. As a concrete example, the diverse data and conclusions concerning the effect of epinephrine on the glycogen content of the liver might be cited. When it is realized that hepatic activity is usually rapid, particularly so in response to many substances such as epinephrine, and that, in many of the investigations, a determination of the glycogen content of the liver was made a considerable time after administration of the epinephrine, the causes for confusion with regard to this question are readily understood.

HEPATIC ACTIVITIES IN RELATION TO THE INGESTION OF FOOD

Gross changes in the liver. The rôle of the liver as the provider of the body begins immediately after the ingestion of food and is definitely portrayed in the difference between its gross appearance in the fasting and digesting states. The liver of the fasting animal appears smaller than is usually considered normal and lacks somewhat its characteristic color. The edges of the organ are sharp. If the fast has extended for a few days, in many species a characteristic fatty appearance develops. The liver of the digesting animal, while affected somewhat differently by various foodstuffs, appears larger than the liver of the fasting animal. It has the characteristic dark-red or pale-red color, depending on the time after food is taken; its tissue is very friable and its edges are slightly rounded. A picture of the most extreme differences which are usually noted can be observed by comparing the liver of an animal of a species that hibernates, when in the digesting state, and that of an animal of the same species after the latter has hibernated for several days. The liver of the former presents the appearance which is usually regarded as normal, whereas that of the latter appears to be in a most extreme fatty condition. The appearance of the liver in the latter instance will again be normal within a remarkably short period after taking food.

The diurnal cycle. The variation of hepatic activity in relation to the ingestion of food has indirectly been quantitated by determination of the major constituents of the organ at various periods of time after feeding. Forsgren (1), using a histologic technic, observed in the livers of rabbits a cyclic activity which he considered to involve the glycogen-forming and bile-secreting functions. He interpreted his observation as indicating that the secretion of bile alternates with the deposition of glycogen, and that these two functions were not regulated merely by nutrition but were probably correlated in some way with a rhythmic activity in the digestive organs. He believed that during the night there was a maximal deposition of glycogen and a minimal formation of bile and that during the day the reverse condition prevailed. He designated these two alternating functions as the "assimilatory" and "secretory" phases of the cycle and concluded that they were not dependent on the ingestion of food.

*Nineteenth McCon Lecture delivered before the Society for Biological Research of the School of Medicine, University of Pittsburgh, April 26, 1935.

†Division of Experimental Medicine, The Mayo Foundation.

Agren, Wilander and Jorpes (2) described cyclic changes in the glycogen content of the livers of rabbits, rats and mice, changes which they believed were largely independent of food intake. Glycogen accumulated in the liver during the night and disappeared to some extent the next morning. Similar conditions occurred even in fasting animals. These authors studied the cyclic variations in the glycogen of the liver of mice and rats under continuous feeding and during fasting, but did not study changes which ensue following a restricted period of access to food and water. Thus Forsgren, Agren, Wilander and Jorpes were of the opinion that the cyclic changes in the liver are independent of feeding but are largely dependent upon astronomic factors.

Higgins, Berkson and Flock (3) noted that when rats were given free access to food, all individuals did not eat at the same time, so that it was not possible under such conditions to have all animals in a large group in the same stage of the digestive cycle. To overcome this difficulty they trained the rats to eat at a definite time by permitting them access to food for a two-hour feeding period from 9 to 11 a. m. After the animals were fed in this manner for a sufficient time, groups of them were sacrificed under standard conditions every two hours for a period of twenty-four hours; the weight of the liver was recorded and a chemical determination was made of some of the major constituents of the liver that might vary with the ingestion of food. They observed that, after the feeding the weights of the liver passed through a series of changes which followed a characteristic form. An increase in the weight of the liver began soon after the taking of food and reached a maximum in the early evening or about six hours after food and water were withdrawn. A transient fall in the weight of the liver was then recorded, followed by a second rise which reached its maximum about 1 a. m. From this time on a gradual decline in weight of the organ occurred throughout the remainder of the night, so that, at 7 a. m., weights were recorded at essentially the prefeeding level of twenty-two hours before. Thus the curve depicting these changes was bimodal. Chemical analysis of certain of the constituents of the liver showed that the changes in the weights of water, glycogen and protein followed a similar rhythmic variation as the total weight of the organ.

Subsequently, Higgins, Berkson and Flock (4) further studied the relation of feeding to these cyclic changes in the liver. They trained groups of rats to eat and drink for two hours progressively for twenty-four hours. Ten rats were trained to eat from 9 to 11 a. m., ten from 11 a. m. to 1 p. m., ten from 1 to 3 p. m., and so forth. After a ten-day training period all rats were sacrificed six hours after eating 10 gm. of food. In preliminary training, duration of feeding, amount of food consumed and time of sacrificing after feeding, all rats were alike. The only varying factor was the time of day the animals were fed. Under these conditions, the curve of changes in the weight of the liver and in its glycogen and water content was practically a straight line.

In a more recent study Higgins (5) determined the changes at two-hour intervals in the weights of the livers of rats that had been maintained in total darkness and on a restricted two-hour feeding period for several weeks prior to the final experiment. He obtained a curve of cyclic changes similar to that found in the first mentioned investigation of Higgins, Berkson and Flock. In other words, the liver underwent changes in weight in relation to the ingestion of food in the case of animals kept in darkness exactly the same as in animals maintained under normal conditions. He also found that the type of curve was affected differently by various foodstuffs.

These studies on the diurnal cycle prove that there is a marked change in the quantity of some of the constituents of the liver in relation to the digestive cycle. It must not be assumed that all such changes involve only the food actually ingested. It is possible that a plethora of foodstuff entering the circulation may cause a rearrangement of previously deposited food stores in the body. However, carefully controlled studies of the diurnal cycle, using food substances that can be labeled such as some of the recently utilized isotopes, offer the possibility of determining more definitely the fate of various foodstuffs and the part the liver plays in their immediate storage and distribution.

Histology and cytology of the liver. While histologic studies of the liver have emphasized the rapid changes that occur in the demonstrable quantity of the important stored foodstuffs, they have given at best but an imperfect picture of what occurs during the sojourn of such stored foodstuffs in the organ. It is relatively easy to demonstrate microscopically a certain amount of glycogen and fat in the hepatic lobule. Protein deposition has not been conclusively demonstrated in the hepatic cell, although Noël (6) described star-shaped granules which he concluded were a deposit form of this foodstuff. It has not been so easy to agree on the manner in which these substances are deposited. According to Noël, all the hepatic lobules are functioning within two hours after the ingestion of food. The current view in regard to the manner in which glycogen and fat are laid down in the hepatic lobule is as follows (7): When glycogen is being formed in increasing amounts in the liver, it appears first and in more abundance in the cells of the lobule adjacent to the central vein and, as more glucose becomes available, the glycogen accumulates in the other hepatic cells, those around the periphery of the lobule being the last to obtain their store. In general, the withdrawal of glycogen takes place in reverse order from the course of its deposition, the cells around the central vein appearing to retain glycogen longest. The distribution of glycogen in the hepatic cell is not uniform but, usually, glycogen granules are not found on the periphery or in the nuclei. The fat deposited in the hepatic lobule presents varied pictures. It is not possible at present to state how much of the microscopically demonstrable fat is part of the fat ingested in the previous meal or fat mobilized from other fat depots of the body. It is also impossible to distinguish without other criteria such as necrosis whether the fat in the hepatic cell is of physiologic or pathologic significance. In general, the fat which appears in the hepatic cell after the ingestion of large amounts of fat occurs in the form of globules, and their distribution in the lobules is quite variable. The fat which is demonstrable in the hepatic cell after injury usually first appears as granules. The amount of fat that can be stored in the hepatic cell and demonstrated microscopically is truly enormous. In a hibernating animal, every cell in the lobule may be so completely distended with fat that the nucleus will be pushed to the outside

of the periphery, giving the so-called signet-ring appearance. It is often possible, particularly in the liver of a fasted animal, to demonstrate large amounts of fat in the cells lining the intrahepatic bile ducts. The significance of this is not known.

Cytologic studies of the liver have demonstrated that definite and rapid changes occur in the hepatic cell, not only in relation to the ingestion or withdrawal of food, but also depending upon the kind of foodstuff ingested. Even a cursory cytologic study of the liver of a carbohydrate-fed animal and of a fat-fed animal will demonstrate characteristic changes differentiating them from each other. It is also possible to differentiate cytologically the liver of a fasted animal from that of a well-fed animal. However, many of the studies of the protoplasmic details of the hepatic cells in relation to the ingestion of food have given contradictory results. There are several reasons for the failure of cytologists to see everything alike, and when the complexity of the hepatic cell and the multiplicity of its activities are taken into consideration, it is rather surprising that there is so much agreement.

In this connection it should be noted that the changes in the hepatic cell are occurring relatively rapidly; that these changes involve elaboration of substances, some to be transferred to the blood or lymph and others to be excreted in the bile; that there is a constant checking-in or checking-out of different kinds of storage material, and that the rate and character of the activity of the hepatic cell at any given time is dependent upon many variable factors which are almost impossible to maintain constant for any great length of time. As an illustration it should be noted that the finer details of the arangement of the protoplasm of an hepatic cell containing little storage material may not be due to any specific change in the structure of the cell but rather to the ability to see such details better in the absence of the storage material. However, if sufficiently extreme conditions of hepatic activity are taken for comparison, definite differences in the cytologic appearance of the hepatic cell in relation to the ingestion of food can be demonstrated, as Altmann (8) showed so many years ago in the livers of frogs in the summer and winter seasons. It is probably expecting too much of the method to corroborate in all their minute details the observations of some cytologists like Noël.

The statements just made in regard to the general cytologic details of the hepatic cell apply with equal force to the special cytologic structures, the mitochondria. The question of the significance of mitochondrial changes in relation to hepatic cell activity is as yet not answered. It appears quite probable that changes in the number, shape and distribution of mitochondria do occur in relation to the ingestion of food; the specificity of such changes, however, is still open to question, although the evidence presented in regard to a relationship between the mitochondrial morphology of the hepatic cell and the glucose-glycogen equilibrium is very suggestive (9, 10). The statement of Kater (11) that the actual explanation for the changes in the mitochondria of the liver which accompany digestion must still be regarded as elusive, expresses the present status of the problem very succinctly. The significance of the Golgi apparatus in relation to hepatic cell activity is still open to question (for a review of the recent literature refer to Weatherford (12)).

I do not wish to leave the impression that histologic and cytologic studies of the liver have been without value or that such studies may not be a profitable method of obtaining new facts in regard to hepatic activity in relation to the fate of the different foodstuffs. As a matter of fact, probably none of the usual methods of investigating the liver, and few that offer more fruitful results, is being used less at present than cytologic research. The main difficulty in the past appears to have been that the cytologists have not employed standard and controlled physiologic procedures. I agree with Kater (11) that, if the results of a cytologic investigation are to be of value, the physiologic data must be as accurate as the cytologic observations. Many of the older researches should be repeated using standard methods of feeding and the newer knowledge of diets. Noël's conclusion, made from his studies on the mouse, that part of all the hepatic lobules are functioning within two hours after ingestion of food, should be investigated using other species of animals. If this conclusion were correct, it would indicate that the variations in hepatic function and hepatic reserve depend on differences in activity of different zones of cells within the lobule and not upon entire lobules, thus signifying that, physiologically, an hepatic trabecula is the functional unit of the liver and not the lobule. In this connection it should be determined beyond any question of doubt in what cells of the trabecula of the liver of the fasted animal glycogen is first formed after the ingestion of carbohydrate, and likewise, the site of the cells in which glycogen is first to disappear in the beginning of a fast. Similar observations should be made in regard to the changes in demonstrable fat in the fasting state and after feeding fat. It should be determined whether the star granules do indicate the deposit of protein as Noël concluded.

It should also be noted that the cytologists have not proved from the physiologic viewpoint that the secretion granules which they consider as bile really is the external secretion of the gland (12). It would be of considerable value to have an accurate cytologic picture of the transformation of the hepatic cell completely filled with fat to the usual type of cell seen when the animal is eating a mixed diet. It is possible that enlargement of knowledge concerning the significance of the mitochondria of the hepatic cell may give an answer to some of the most important questions concerning hepatic function. As an illustration the observations of Kater and Smith (13) can be cited in which they noted the formation of fat globules in the mitochondria after the feeding of cane sugar. This would appear to be suggestive evidence for the long held but never proved theory that the transformation of carbohydrate to fat occurs in the hepatic cell. Finally it should be emphasized that it is impossible to quantitate stored food material as glycogen and fat in the liver by microchemical methods. Any investigator who has attempted to estimate the quantity of these substances in the liver microscopically and had his efforts checked by chemical analysis realizes that he may be 100 per cent wrong.

STORAGE OF FOOD MATERIALS

The liver is the storehouse of utilizable food for the body as a whole. While food is stored in other tissues of the body, such stores are either limited to consumption by the tissues in which they are stored, such as

glycogen in muscle, or are apparently only used when ingested food and the hepatic supply is decreased, such as protein and fat. In this respect the liver can be compared to the pack containing the daily ration on the back of the soldier.

Carbohydrate. It has been known for almost a century that there was a storage form of carbohydrate, glycogen. This substance is normally stored in amounts sufficient to be considered a food depot in muscle and liver. The total amount ordinarily stored in each of these tissues is approximately equal, but the percentage amount is much greater in the liver. While the ultimate fate of a large proportion of the glycogen stored in the two depots is probably the same, that is, of being burned in the voluntary muscles, their physiologic significance is quite different: Only the glycogen in the liver is capable of being transformed into glucose and of being mobilized for direct utilization by all the cells of the body (14).

The amount of glycogen stored in the liver varies within wide limits even in the normal animal depending upon several factors, the most important of which are the amount and character of food ingested, the extent of bodily exertion and the species of animal. Changes in the glycogen content of the liver can occur very rapidly. It would appear to be very rare indeed for the liver to be devoid of glycogen. The maximal amount of glycogen that can be stored in the liver greatly exceeds the amount usually found. Butsch (15) injected large amounts of glucose intravenously into dogs at a constant rate until the glucose tolerance was broken. He found that the liver could store glycogen under the condition of his experiments to a maximum of 20 to 25 per cent. Pollack and associates (16) as well as Soskin and associates (17) have shown that the glucose capacity of the dehepatized animal is much less than that of the normal animal.

Protein. Whether or not there is a form of storage protein similar to glycogen as the storage form of carbohydrate and fat as the storage form of this food substance has been a debated question. A brief review of the more pertinent investigations on the subject has been given by Luck (18). The fate of ingested protein appears to be fairly well determined up to a certain point, but from there on we have at best only conjecture. Protein is absorbed from the gastro-intestinal tract in the form of amino-acids. Most of the amino-acids are stored temporarily in the liver, a small amount in the involuntary muscles (19). A certain proportion of these amino-acids are built back into the body protein of the individual ingesting them. The amounts so utilized depend on many factors, such as whether the individual is growing, the nutritional condition, character of the diet and so forth. The excess amino-acids not thus utilized are deaminized. Under normal dietetic and nutritional conditions in the adult a very high percentage of the amino-acids appears to be deaminized shortly after ingestion. The question is whether or not some of the amino-acids are used to make a special storage form of protein.

The most recent work on this problem is that of Luck (19), which would indicate insofar as the liver is concerned that no single protein or fraction of the hepatic protein can be regarded as reserve material in the sense of being chemically distinct from the basal structural protein of the organ. Luck maintained a group of rats on a low protein diet and another group on a high protein diet. The livers of each group were removed and the basal protein of the organ quantitated under controlled conditions. He found that the rats maintained on a high intake of protein had an increased content of protein per unit weight of hepatic tissue, but that each of the basal protein fractions increased in equal amounts as compared with their values in the livers of rats on a restricted intake of protein. These results would indicate, within the limits of present chemical methods, that all of the hepatic proteins participate equally in the function of storage.

While the evidence is definitely unfavorable to the view that a special deposit form of protein exists, there is no question but that the body may contain a considerable amount of protein which can be used for fuel without seemingly altering the protoplasmic activity of the body cells. Several methods have furnished evidence in regard to the presence of deposit protein, the most important being studies made during fasting, in metabolic diseases, particularly diabetes, and those made by Boothby (20) and his coworkers on thyroxin. In all these conditions there is a period in which nitrogen elimination exceeds nitrogen intake. Probably all the cells in the body are drawn upon for this protein for fuel in time of metabolic stress. The liver appears to be drawn upon more heavily than other tissues of the body. Addis (21) and his coworkers have recently quantitated the total protein lost from various tissues of rats during fasting. They found that after a seven-day fast the amount lost varied from 62 per cent of the total coming from the muscle, skin and skeleton, 16 per cent from the liver, to 0.5 per cent from the heart. On the other hand, the liver lost 40 per cent of its total protein, which was a much greater less than for any other tissue. The same author (22) also found that, after a two-day fast, the liver lost 20 per cent of its original protein whereas other organs lost only 4 per cent. These results definitely indicate that the liver is the site from which protein for fuel is first, and to the greatest degree, withdrawn and that the liver is the true storehouse for protein.

Fat. The fat in the liver is of considerable importance, both physiologically and pathologically. On a well-balanced diet the fat content of the normal liver appears to be fairly constant and, in dogs, is about 2.5 per cent. From 40 to 70 per cent of the hepatic fat occurs in the form of neutral fat, and the rest as phospholipids. The fat content of the liver can be increased by feeding a fatty diet and, if the appropriate diet is fed for a sufficient length of time, the fat content of the liver may become as high as 50 per cent. While the total fat content of the liver may be only a small percentage of the total fat content of the body, the hepatic fat may physiologically be of the greater importance.

Changes in the fat content of the liver occur more slowly than those in the glycogen content and possibly also in the protein content. While this difference in rate of mobilization and demobilization makes it possible for the liver to have both a high glycogen and fat content, in general (22) when the hepatic content of one of these storage materials is increasing the other is decreasing, so that they can be said to have a reciprocal relationship to each other.

The fat content of the liver increases in the fasting state provided there is available fat in other fat depots of the body. Hepatic fat is also greatly in-

creased if fat is available in many pathologic states, particularly some of those affecting metabolism and after the administration of hepatotoxic agents such as chloroform or carbon tetrachloride. Alcohol in amounts that cause no change in the livers of animals on a well-balanced diet will cause rapid deposition of fat in the liver when a fatty diet is fed. Sufficient (23) has been stated to show that the liver is a fat depot and that hepatic activity is significant in fat metabolism.

Miscellaneous storage substances. There are possibly numerous important storage substances in the liver, the existence and significance of which are unknown. It is known that hepatic tissue has a high content of certain minerals. While some of these minerals are probably in the hepatic cells, others like iron are found mainly in the stellate cells. There are some data suggesting that the liver may store other substances in a similar manner as it does vitamin D and the active fraction in pernicious anemia.

There is considerable difference of opinion concerning the significance of the variation of the water content of the liver. In most of the discussions of the subject it has not been realized that the liver is probably never doing just one thing, and that the total water content of the organ is a resultant of all the processes occurring at that time. It is obvious, since usually the water content of the liver is high, being approximately 70 per cent, that if another substance accumulates in the organ in very large amounts, such as fat, the percentage of water will necessarily decrease. While in all probability the water content of the liver varies in relation to its various physiologic activities (24) just as in any other tissue, there remains the possibility that the liver has a special function in water metabolism. The literature has recently been noted by Crandall and Roberts (25).

MANUFACTURE OF FOOD MATERIAL

Many food substances pass the barrier of the intestinal mucosa and are absorbed in a form either not capable of being utilized directly by the tissue cells or not utilized as readily as in another form to which they can be converted. It is obvious that some tissues of the body must have the ability to make such conversions. In the case of several substances the conversion occurs in the liver.

Carbohydrate. There is considerable difference in the utilization of the more important sugars that reach the blood stream. Glucose is the sugar of choice for burning in the tissue cells. The liver is of importance in relation to this sugar as regards control of its concentration in the blood and storage, both processes being discussed elsewhere. Levulose can be used directly by the body, as has been proved by experiments with the dehepatized animal (26) although, normally, the liver probably transforms the ingested levulose into glycogen before utilization by the tissue cells. Experiments with the dehepatized animal would indicate that only a small amount, if any, galactose is utilized directly, and that the liver is responsible for transforming it into the more preferable glucose, probably first building it into glycogen (27).

Protein. As previously stated, the amino-acids absorbed from the intestinal tract are stored temporarily, for the most part in the liver and in muscle tissue. The amino-acids which are not used as such to repair tissue cells or to form new proteins are deaminized; the nitrogenous portion is converted into urea and the remaining portion is burned or converted as carbohydrate. The manufacture of carbohydrate from amino-acids as well as the formation of the nitrogenous portion into a form capable of being readily excreted are functions of the liver (28).

Fat. One of the most mooted questions in metabolism is how fat is burned. I shall discuss only those phases of the problem which for the most part center around the question of possible transformation of fat to carbohydrate, because investigations on this problem intimately involve functions of the liver that have been discussed. Two opposite schools of thought have developed in regard to the question of such a transformation, each at one time upheld in this country by an able sponsor, MacLeod being in favor and Lusk against the view that such a process occurred in the body. I believe that the most vivid memories that many of us possess of these two great physiologists, picture them in stirring debate over this question. Lusk obtained data for his viewpoint from his numerous studies on the metabolism of the phlorhizinized dog (29). In such studies the respiration quotient (R. Q.) and dextrose-nitrogen (D. N.) ratio were considered significant constants. MacLeod, accepting the implication in the original Myerhoff-Hill theory of muscle contraction but questioning the value of the R. Q. and D. N. ratio in the sense that Lusk meant them, relied for proof of his viewpoint on various researches dealing with depancreatized and dehepatized animals and on the action of insulin and epinephrine, and so forth. MacLeod (30) several years ago summed up the complete evidence in favor of the view that fat is transformed into carbohydrate before being burned and very little of significance has been added since.

It is now considered that much of the evidence marshalled in favor of each viewpoint is of questionable value in relation to the problem. The phorhizinized dog does appear to metabolize some carbohydrate (31-33); the R. Q. and D. N. (30-34) ratio are capable of other interpretations than that made by Lusk and they may not mean what he thought they did. On the other hand, much of the evidence that MacLeod accumulated in favor of the theory has also been questioned, even the investigation which he considered unassailable, namely, the experiments of Chaikoff and Weber (35) on the effect of epinephrine on the sugar excretion in diabetes. These investigators injected epinephrine into well-fattened, fasted, depancreatized dogs, previously treated with insulin but diabetic at the time of experimentation. More sugar was excreted in the urine than could be accounted for from their estimation of the glycogen stores of the body at the time of injection and from the protein and glycerol metabolized. The logical conclusion was that the excess sugar could have come only from fat. Subsequent investigators found, however, that when the glycogen store in liver and muscle was actually measured in experiments otherwise exactly similar to those of Chaikoff and Weber, all the excreted sugar could be accounted for without hypothesizing a source of part of it from fat (36).

In general the problem is unanswered in its entirety, although there is some recently adduced suggestive evidence on both sides. Drury and McMaster (37) maintained rabbits on a fat diet and then removed the liver. Such dehepatized animals retained an R. Q. which suggested that they were burning fat. Murlin

(38) and associates showed that a transformation of fat to carbohydrate does occur in certain plants. Soskin (39) has interpreted some of the results of his studies on the hypophysectomized animal as supporting this theory. At present it must be concluded that the possibility of the transformation of fat to carbohydrate exists, but evidence is lacking as yet that it actually occurs in the animal organism (40). Probably the most significant statement that can be made in regard to the problem is the one attributed to Pflüger: the farmer feeds his swine carbohydrate in the form of corn and sells it in the form of lard; carbohydrate is undoubtedly changed to fat and there remains the possibility that the reverse can occur.

I have discussed the possible transformation of fat to carbohydrate out of proportion to its proved significance for two reasons: (1) because if it actually occurs it is highly probable that hepatic activity will be found to be involved in the process, and (2) because the question is of such great significance, not only in regard to metabolism but also in relation to hepatic physiology, that continued research is indicated. It is possible that investigations employing the use of appropriate isotopes and studies on animals with one or more of the ductless glands which so profoundly affect metabolism removed will afford an answer.

MECHANISM OF REGULATION

It has previously been emphasized that: (1) the body cells constantly require food materials, reaching them in accordance with their varying needs, and (2) that the liver is an indispensable storage and manufacturing plant for these food materials. There must be some mechanism or mechanisms for regulating: (1) the kind and amount of food substances sent to the tissues to meet their changing requirements, (2) the formation of glycogen and glycogenolysis in the liver, and (3) the manufacture of available food materials in the organ as gluconeogenesis from protein and possibly from fat.

Carbohydrate. Very little is known concerning the intracellular mechanism which transforms various substances into a storage form of carbohydrate, glycogen, and subsequently breaks it down into a transportable and utilizable form, glucose. These processes are in all probability carried out by cellular enzymes, but the chemical steps in the processes and regulation of the rate of glycogen formation and glycogenolysis are at present only conjectural (Cori (41) has given a review of literature).

Considerable is known concerning the importance of the liver in furnishing a constant supply of glucose to the tissues of the body. When the liver is removed from an animal, the glucose concentration of the blood immediately begins to decrease (42). When the glucose concentration has decreased to a low level, the characteristic symptoms of hypoglycemia supervene and, if glucose is not administered, fatal coma develops (43). It is rather discouraging to note that little more is known concerning the cause of the symptoms of hypoglycemia and their rapid alleviation by glucose than was known when Magath and I gave the results of our observations on the dehepatized animal many years ago, despite the fact that insulin has subsequently been found to reproduce an identical condition and symptoms with restoration following the administration of glucose, which has been observed thousands of times both in the case of human subjects and animals, and despite the fact that many clinical cases of hypoglycemia, probably resulting from various causes, have been described. It appears evident that the development of symptoms of hypoglycemia depend not so much on the level of glucose as on the rate at which glucose leaves the blood stream. It has also been proved that hyperglycemias depend upon hepatic activity. Hyperglycemia will not occur in a dehepatized animal following removal of the pancreas, during asphyxia, or after the administration of ether, epinephrine or other substances, or after procedures which increase the blood sugar in an animal possessing a liver (44).

As previously stated, the fate of glycogen in the muscle and liver is different. The glycogen in the muscle is converted into lactic acid and thus fulfills its function in relation to the process of muscle contraction, whereas the glycogen in the liver is converted into glucose and is available to all the tissues of the body. The fate of the excess lactic acid, produced during muscular contraction, which reaches the blood stream is not definitely known. It is undoubtedly true, as Cori (45) and Cori (46) and others have enunciated, that some of the lactic acid passes to the liver where it is rebuilt into glycogen. However, Bollman and I (47) have found that large amounts of lactic acid can be injected into a dehepatized animal which subsequently cannot be found in either the blood or urine. Evidently there is a mechanism for taking care of lactic acid outside the liver.

Protein. Very little can be added concerning the mechanism of protein metabolism relative to the liver than has been given. It should be noted that the liver is important in purine metabolism because the uric acid not excreted in the urine is changed to allantoin in the liver (48).

Fat. In the discussion of fat storage in the liver it was pointed out that the changing fat content of the liver, while occurring more slowly than the changes in glycogen content, was of sufficient magnitude and rapidity to indicate that the liver was an important organ in fat metabolism. Knowledge concerning the mechanism of regulation of the mobilization and demobilization of fat in the liver is as yet meager, although a few important advances have recently been made.

The workers in MacLeod's laboratory at the time they were investigating the action of insulin found that it was necessary to provide fresh pancreas in the diet of depancreatized dogs in order to enable them to live for more than a few months. If pancreas was not fed, the animals died and an excessively fatty liver was the only postmortem finding of note. The feeding of raw pancreas prevented the development of the fatty condition of the liver and death (49). Best (50) and his coworkers, in attempting to determine the constituent in the pancreas which prevented the development of the fatty liver, found that it was in the phospholipid fraction and eventually identified it as choline. They found that they could use the rat for studies on fat exchange in the liver, and they have proved conclusively that choline may be an important substance in the mechanism of regulating the fat content of the liver. By feeding an appropriate diet they could increase the fat content of the liver to a large amount. If sufficient choline was added to the diet, which was otherwise not altered, the fat content of the liver did not increase. Furthermore, if choline was added to

the diet of an animal possessing a liver with a high fat content, the fat was quickly demobilized.

Dragstadt, Van Prokaska and Harms (51) have made an extract of pancreas which does not contain choline, but which also causes rapid demobilization of hepatic fat. Bollman (52) has corroborated these findings of Draagstadt, using dogs in which the fat content of the liver was enormously increased by feeding a fat diet in conjunction with the administration of alcohol. The administration of the extract of Dragstadt greatly accelerated the rate of fat demobilization under such conditions.

The forementioned investigations probably dealt mainly with the neutral fat in the liver, which amounts to approximately 70 per cent of the total fat content of the organ. Flock, Bollman and I (53, 24) have attempted to determine the changes in the phospholipid content of the liver under varying dietetic conditions and experimental procedures. A considerable part of our efforts were necessarily directed toward methods of quantitation and experimental procedures as free as possible from the numerous sources of error encountered. Very few positive statements can be made at present. The total phosphate content of the liver remained remarkably constant under most of the conditions studied, the most marked change being a decrease with a high fat diet that produced extremely fatty livers. Of the important phosphate fractions of the organ, the phospholipids varied least.

I have attempted to convey in this brief review (1) that the exchange of fat in the liver is an extremely important process, (2) that it is difficult of investigation, and (3) that some progress is being made, although not commensurable to the importance of the subject.

HEPATIC ACTIVITY AND GENERAL METABOLIC PROCESSES

While the mechanisms regulating the passage of foodstuffs to and from the liver are not known, it is justifiable to postulate that they exist and that the utilization of food by the tissues is closely correlated in some manner with hepatic activity. There are suggestive evidences that variations in the kind and amount of food utilized by the tissues are reflected in changes in the functions of the liver. Investigation of these possible mechanisms is difficult because, in order to evaluate the kind and rate of utilization of the various foodstuffs in the body, reliance must for the most part be placed on the respiratory quotient, an interpretation of which has been called into question. However, there are some data on the question which are suggestive and interesting.

It requires 0.25 gm. of glucose per kilogram of body weight to maintain the normal concentration of glucose in the blood of a dehepatized animal, which previous to operation had been on a normal diet, for the first few hours after loss of the liver (54). This can be interpreted as meaning that a normal animal on a mixed diet requires such an amount of glucose. Care must be used in such an interpretation because factors other than the normal utilization of glucose appear to be present. While 0.25 gm. of glucose per kilogram of body weight will maintain the blood sugar at the normal level for the first few hours after removal of the liver, it soon is necessary to increase the amount of glucose until, thirty hours after operation, it usually requires 1 gm. of glucose to maintain the animal in normal condition. If the animal has been kept on a high carbohydrate diet before removal of the liver, it usually requires a larger amount of glucose initially, whereas if the animal has been fasted for a considerable period of time prior to operation, the glucose requirement is less than if a standard mixed diet had been used. Furthermore, when the liver is removed, the respiratory quotient increases toward unity (55), possibly indicating that the dehepatized animal meets its energy needs with a larger percentage of carbohydrate than the normal animal. The specific dynamic action of glucose and amino-acids varies from normal in the dehepatized animal. The specific dynamic action of a given amount of glucose is enhanced in the animal without a liver as compared with the results obtained in the same animal before removal of the liver (55). On the other hand, injected amino-acids do not cause a specific dynamic action in the dehepatized animal (56).

Other more or less uncorrelated facts could be cited, but sufficient has been given to illustrate the complexity of the metabolic processes in which the liver has a part and that hepatic activity responds to the varying metabolic needs of the organism. I believe it can be accepted as a general conclusion that the liver probably does not control any of the metabolic processes but simply responds to the changing metabolism of the organism as a whole.

RELATION OF HEPATIC ACTIVITY TO THE VARIOUS ORGANS OF INTERNAL SECRETION

It has been considered for many years that the functions of the organs of internal secretion have to do mainly with various phases of metabolism, but only recently have adequate data been presented to demonstrate the complexity of the mechanisms involved. Such data deal mainly with the results of studies on animals from which one or more of the glands of internal secretion have been removed. It would diverge too far from our purposes if more than a brief review of these data were presented, even if knowledge of the subject were not in such a bewildering state as at present. However, since the liver is so important in many metabolic processes, and since the loss of one or more of the glands of internal secretion affects some of the phases of metabolism in which the liver is involved, a few statements of apparently known facts should be given:

Removal of the pancreas, as was learned half a century ago, produces the marked hyperglycemia and glycosuria of pancreatic diabetes. Removal of the hypophysis results in failure to maintain carbohydrate during fasting (57). Removal of both adrenal glands is said to be followed by hypoglycemia and a marked reduction in glycogen in muscle and liver (58). Such findings have only occasionally been noted in our laboratory in adrenalectomized dogs. Removal of the pituitary (59) and the adrenals (60) from a depancreatized animal restores the diabetic animal to a more nearly normal condition as regards carbohydrate metabolism, that is, there is a marked reduction of glycosuria together with its disappearance on fasting, a marked reduction of nitrogen excretion during fasting, and almost complete disappearance of acetonuria and acidosis. These results have been explained in various ways and probably the best theory is that loss of the pituitary and adrenals decreases the rate of

gluconeogenesis from protein or fat in the liver. This theory is as yet not proved.

While much more could be written in regard to the recent work on this phase of the subject, this brief and incomplete review should suffice to illustrate the complex mechanisms of metabolism in which hepatic activity is probably either directly or indirectly a part. It is impossible to say how liver function is affected by various hormones, although a few general statements can be made. Hepatic activity can be changed by hormones in the following respects: (1) by an effect on the rate of body metabolism, (2) by an effect on the intrinsic mechanism of the liver, either for storage or manufacture of food, and (3) by an effect on the amount of available food materials reaching the liver. At any rate it is evident that a great discovery in metabolism will have been made when the rôle of the liver in relation to the action of the various hormones on metabolic processes has been explained.

MISCELLANEOUS ACTIVITIES OF THE LIVER

There are many physiologic processes in the body which, mainly because of lack of definite information concerning them, are said to occur in the liver or said to be due to hepatic activity. While several of such processes might be discussed, only a few in which it appears highly probable that the liver is actually involved and which are pertinent to our subject will be presented:

Cholesterol. One of the most outstanding of these enigmas is cholesterol. The liver is undoubtedly a factor in cholesterol metabolism because this substance is one of the important constituents of bile. But in spite of the large number of investigations and their resulting theories of cholesterol metabolism the rôle of the liver in this process is conjectural.

Bile salts. Considerably more is known concerning hepatic activity in the metabolism of bile salts than in that of cholesterol. A résumé of the literature on the metabolism of bile salts has been given by Sterner, Bartle and Lyon (61). Whipple and Smith (62) concluded from their studies on animals with complete biliary fistulas that bile salts are constant under constant dietary and physical conditions, that dietary factors may affect the amount of bile salts formed, that bile salts administered by vein or by mouth are rapidly and quantitatively excreted in the bile, that the liver is responsible for the elaboration of bile salts, and that slight injuries to the liver may greatly reduce the amount of bile salts formed and excreted. Bollman and I (63) investigated the metabolism of bile salts under various experimental conditions and obtained the following results: The normal dog excretes but traces of bile salts in the urine, and bile salts are not definitely detectable in normal blood. Following intravenous injection of glycocholates or taurocholates only a small portion appears in the urine and the injected material rapidly disappears from the blood. After continuous administration of large amounts of bile salts the indication is that destruction of these substances takes place, since only traces are found in the urine in feces. After complete removal of the liver, bile salts are not found in the blood or urine even after periods of time in which they are readily detected following ligation of the common bile duct. The liver appears to be the site of formation of bile salts. After complete removal of the liver, injected bile salts are rapidly excreted in the urine, so that quantitative recovery of the injected material is usually made within twelve hours. If similar injections are made in animals with biliary obstruction, only part of the injected material can be recovered. The liver apparently plays a predominant part in the destruction of bile salts. The formation of bile salts is inhibited by administration of hepatotoxins such as chloroform, carbon tetrachloride, or tetrachlorethane, but is not affected by other toxins such as toluylendiamine. Destruction of bile salts is little altered by hepatotoxins that markedly alter the formation of bile salts.

Blood proteins. The relation of the liver to the formation of the blood proteins is another disputed question. A fine review of the investigations on this problem has recently been made by Reimann, Medes and Fisher (64). The conclusions made from the results of the large number of researches on the question are remarkable mainly because of their contradictions. However, when all the evidence is considered, it appears probable that the liver is in some manner involved in the formation or mechanism of regulation of the blood proteins, particularly fibrinogen (65). It is either not the sole site of their formation, or other tissues have the capacity of storing them in relatively large amounts. It is possible, as Reimann, Medes and Fisher suggest, that the liver is responsible for elaboration of protein precursors of the blood protein, which are incorporated in widely-distributed cells. It is evident that more research is required before the rôle of the liver in such processes as edema and coagulation of the blood can be enunciated.

Ketone bodies. The liver is an important, and possibly the only site of formation of the ketone bodies. It has been found that these substances rapidly disappear from the blood of diabetic animals after removal of the liver (66). They have also been noted to be formed from appropriate precursors when the latter were perfused through the liver (67). As previously noted, their production is decreased in the diabetic animal from which the pituitary or adrenals are removed. The mechanism and physiologic significance of their formation are as yet debated.

Heparin. Heparin, which was discovered by Howell and Holt (68), appears to be a definite product of hepatic activity. Whether its origin in the liver can be in any way related to the possible origin of fibrinogen at the same source is open to speculation.

Anti-anemic factor and hemoglobin. The presence of the anti-anemic factor in such large amounts and the potency of liver tissue in the restoration of hemoglobin, as the excellent investigations of Whipple and Robscheit-Robbins (69) and others have proved, indicates that the liver is of great importance in pigment metabolism.

RELATION OF HEPATIC ACTIVITY TO DISEASE OF METABOLISM

The liver has a necessary part in so many of the processes of normal metabolism that it would appear justifiable to conclude that the organ is involved in many of the diseases of metabolism. In all probability it is rare that hepatic impairment is the primary cause of the disease, but rather that disturbances in the processes of normal metabolism produce changes in hepatic activities in order to meet the altered metabolic requirements of the body. The subject of the relation of hepatic activity to the various diseases of

metabolism requires summarization of existing data and further research before accurate conclusions can be made. However, there are a few outstanding examples of metabolic disease, of which diabetes is probably the best, in which the liver is signally involved. As was previously stated, the hyperglycemia of the depancreatized animal depends upon activity of the liver and the hypoglycemia due to insulin will occur without the presence of the liver, although restoration of the blood sugar after the administration of insulin depends upon the liver. It is as yet questionable whether insulin has a direct action on the liver and whether hepatic activity in pancreatic diabetes is anything more than the response for an increased need of glucose to maintain a hyperglycemia in the presence of tremendous losses of sugar. In view of the proved necessity of the liver for maintaining the known hyperglycemias, it is reasonable to suppose that if forms of diabetes other than pancreatic diabetes *do* exist, as seems probable, the liver is also involved in those instances in which they occur.

Other examples than diabetes could be given, but sufficient evidence has been presented to justify the statement that, in many of the alterations of the processes of normal metabolism, hepatic activity responds to meet the changing needs of the body for a constant supply of food. Investigation of liver function in the various diseases of metabolism offers a fruitful field of research, but it awaits the development of more accurate methods of quantitation.

EFFECT OF DECREASED HEPATIC TISSUES ON LIVER FUNCTION

There are several methods of decreasing the amount of hepatic tissue. The remaining hepatic substance may be normal, atrophic, or cirrhotic, depending upon the method used to decrease the size of the organ (71). Regardless of how the hepatic tissue has been decreased, the functions of the organ, which have been previously given, persist in an apparently normal manner even with relatively small amounts of hepatic tissue. It requires less than 20 per cent of the normal amount of the organ to maintain its functions (72).

CONCLUSIONS

I have assumed that the purpose of the Mellon Lecture was not only to present the results of recent investigations on a specified subject, but also to review, evaluate, and attempt to correlate the significant and applicable existing data in such a manner that the imagination would be stimulated, giving birth to renewed efforts of inquiry. With considerable misgivings I have attempted to do this in regard to the rôle of the liver in the mechanism of maintaining a constant supply of utilizable food materials for the body tissues. While only partial success has been attained, I believe that sufficient evidence has been presented to indicate the importance of the liver in this mechanism, that hepatic activity must be considered as a possibility in every phase of metabolism, and that existing knowledge of the subject is only a small percentage of what must be learned before all the intricate processes involved are fully understood.

I should like to leave with you a picture of the liver as a large storage and manufacturing plant, constantly teeming with activity. Through its vast sinusoids, which are in intimate relationship with the multitude of hepatic cellular units, are transported the various materials upon which the tissues of the body must rely for their source of energy, growth, and repair and for the necessities for maintaining the processes of life. Some of these substances are capable of being used directly by the tissue cells and the liver only stores them during periods of plethora. Other substances are more crude and the liver transforms them into a utilizable form. One must imagine that within the hepatic cell are tools, probably enzymes, for making possible the storage and manufacture of these essential substances. Coming to the hepatic cells must be numerous chemical messengers to correlate hepatic activity to the varying needs of the body. Finally it should be noted that this vital stream to and from the liver must persist, even during dearth of material, bodily disease, and hepatic impairment, as long as life exists. Surely the liver can rightfully be called the provider of the body.

Phenolphthalein as a Dilution Indicator in Gastric Analysis*

By

FRANKLIN HOLLANDER, Ph.D., ABRAHAM PENNER, M.D.

and

MAX SALTZMAN, B.S.

NEW YORK, NEW YORK

IT is generally recognized that the acidity of a specimen of stomach contents, obtained in the course of a gastric analysis, is not a true measure of the gastric response under the conditions indicated. This is so because each such sample contains a variable and indeterminate proportion of the original test meal as well as of saliva and regurgitated duodenal contents. For example, in the course of a Rehfuss series the proportion of test meal present in any one gastric sample may vary from zero to 80 per cent or more of the total volume, according to Bloomfield and Keefer (1), whereas in the one hour specimen obtained by the single aspiration method, Gorham (2) has reported the presence of as much as 60 per cent of the original test meal. As yet we possess no satisfactory technique for evaluating the second and third of these contaminants, but dilution by the test meal can be estimated very simply. For this purpose, it is necessary only that the test meal contain some non-toxic substance, the concentration of which can be measured easily and reliably, and which is known not to be lost in the stomach either by absorption or by chemical combination. A variety of such substances, designated as *dilution indicators*, have been proposed from time to time and in some cases used quite extensively. One of these is phenolphthalein (Lanz (3), Bloomfield and Keefer (4)), the concentration of which can be estimated with a precision of 1 per cent by adding a uniform amount of alkali (e.g., 1 ml. of 0.1 N NaOH to 10 ml. of solution) to convert it to the red alkali salt, and then comparing the color intensity with that of a solution of known concentration in a colorimeter. Because of its obvious advantages over other dilution indicators, especially the fact that it is colorless at pH values less than 8 and therefore will not interfere with the use of other titration indicators for the determination of free and total acidities, we decided to employ it in a series of investigations which were being planned.

It is generally known that the solubility of phenolphthalein in neutral and acid aqueous solutions is rather low. For distilled water, Fantus and Dyniewicz (5) give values of 0.3 mgm. per 100 ml. at 25° C. and 0.6 mgm. per 100 ml. at 38° C.; in 7 per cent alcohol, the solubility at 25° is about 0.8 mgm. per 100 ml. (by interpolation). On the other hand Utz (6) is quoted as having reported a value of 2 mgm. per 100 ml. in neutral water at ordinary temperatures and about 20 mgm. per 100 ml. "when warmed." We were unable to verify these latter values because the original refer-

*From the Laboratories of The Mount Sinai Hospital, New York City. Submitted May 10, 1937.

ence was not available to us,† but since phenolphthalein had been reported by others as being satisfactory we assumed that no difficulty need be anticipated in respect to its low solubility in non-alkaline solutions.

Concerning the standard of reference employed in these experiments: In general, alkalinized phenolphthalein is known to lose color on standing (Lund (9), Thiel (10)), due probably to the conversion of the red

TABLE I

Illustrative experiment to show the loss of indicator from an alcohol-phenolphthalein test meal on standing

Time interval (hours)	0	½	1	1¾	2¼
Concentration of phenolphthalein (mgm. per 100 ml.)	10.0	8.0	7.8	7.4	6.7
Loss of phenolphthalein (per cent of the initial value)	0	20	22	26	33

Accordingly, we prepared a test meal of 7 per cent alcohol which contained 0.01 per cent (10 mgm. per 100 ml.) of phenolphthalein, by diluting a 1 per cent solution in 95 per cent alcohol with the requisite amount and concentration of dilute alcohol, following the procedure employed by previous workers. The immediate result was a clear solution without any evidence of precipitation, but at the end of one hour a portion of the test meal which had been retained as a standard of reference for colorimetry showed a distinct settling out of a white solid. By the end of a second hour, this precipitation had become considerable and contact of some of the solid with alkali left no doubt of its being phenolphthalein. Such a precipitation of the indicator, if it occurs directly from the alcohol test meal, is certain to occur also on dilution of the latter with water and particularly with acid stomach contents — thus completely invalidating the use of this substance as a dilution indicator.

In order to confirm the above observation, therefore, the following experiment was performed. A stock solution of the alcohol-phenolphthalein test meal was prepared in the usual way. From time to time a sample of this stock solution was drawn off, filtered rapidly, alkalinized, and compared in the colorimeter with a standard solution of the initial concentration which had been similarly alkalinized. To insure the development of maximum color on alkalinizing, enough NaOH was added to bring its final concentration up to 0.01 N, corresponding to a pH of *circa* 12 (Michaelis and Gyemant (8)). Since the temperature and the conditions of movement of the reaction flask were not controlled, an experiment such as this one is not quantitatively reliable in respect to the kinetics of precipitation, but it is none-the-less adequate for our present purpose. The results of a typical experiment of this kind, summarized in Table I, leave no doubt of the validity of our initial observation regarding the progressive precipitation of the indicator; in the first half hour the loss of solute was 20 per cent of the initial concentration, and it increased progressively thereafter. There is no apparent reason for expecting that this precipitation will not occur in the stomach as well as *in vitro*. Part of the solid will remain behind in the gastric cavity; but even that disproportionate amount of solid phenolphthalein which may be withdrawn with each specimen will be filtered or centrifuged off with the mucin and other solids and thus lost in the determination. In view of this irregular and unavoidable loss, it must be concluded that phenolphthalein cannot be employed as a dilution indicator.

†We have since discovered that Seidell (7) quotes Utz as reporting a value of 2 mgm. per 100 gm. in neutral water.

di-sodium salt in the quinoid form to the colorless trisodium salt. That the rate of loss of color is relatively great even when the concentration of alkali is as low as at pH 12, may be seen from the experiment illustrated in Table II. In the first half hour of standing

TABLE II

Experiment to illustrate the loss of color of alkalinized phenolphthalein (10 mgm. per 100 ml.) on standing in 0.01 N NaOH, as determined by comparison with freshly prepared standards of reference*

Time interval (hours)	0	½	1	3½
Colorimeter reading	20.0	22.0	22.8	24.6
Loss of color (per cent of the initial value)	0	10	14	23

*This is estimated to be the lowest concentration of alkali which will effect complete conversion of the phenolphthalein to its red salt form, and corresponds to pH 12.

at room temperature, one such solution lost as much as 10 per cent of its initial intensity of color; after the second half hour, this loss had increased to 14 per cent. Consequently, in the experiments similar to that of Table I it was not possible to employ the same portion of solution as colorimetric standard throughout the entire series of observations. Instead, a fresh color standard was prepared simultaneously with each of the unknown solutions, and readings were made with sufficient rapidity to eliminate any significant amount of this decolorization in either the standard or the unknown. This spontaneous decolorization of the alkalinized phenolphthalein acquires further significance by reason of the fact that, unless the unknown solutions as well as the standards of reference are alkalinized only a short time before being read, the phenomenon may constitute another source of error of considerable magnitude.

CONCLUSION

We have demonstrated the existence of two possible sources of error in the use of phenolphthalein as a dilution indicator in gastric analyses. (1) The solubility of phenolphthalein in the acid form, both in water and in dilute alcohol, is considerably lower than the concentration which it is necessary to employ in a test meal. Even if the latter be prepared immediately before it is administered to the subject, in the course of a two hour Rehfuss series determination a considerable amount will be lost by precipitation in the stomach and by filtration of the specimens to remove mucin and other solids preparatory to colorimetry. (2) Phenolphthalein, at a concentration of 10 mgm.

ence was not available to us.† But since phenolphthalein had been reported by others as being satisfactory we assumed that no difficulty need be anticipated in respect to its low solubility in non-alkaline solutions.

Concerning the standard of reference employed in these experiments: In general, alkalinized phenolphthalein is known to lose color on standing (Lund (9), Thiel (10)), due probably to the conversion of the red

at room temperature, one such solution lost as much as 10 per cent of its initial intensity of color; after the second half hour, this loss had increased to 14 per cent. Consequently, in the experiments similar to that of Table I it was not possible to employ the same portion of solution as colorimetric standard throughout the entire series of observations. Instead, a fresh color standard was prepared simultaneously with each of the unknown solutions, and readings were made with sufficient rapidity to eliminate any significant amount of this decolorization in either the standard or the unknown. This spontaneous decolorization of the alkalinized phenolphthalein acquires further significance by reason of the fact that, unless the unknown solutions as well as the standards of reference are alkalinized only a short time before being read, the phenomenon may constitute another source of error of considerable magnitude.

CONCLUSION

We have demonstrated the existence of two possible sources of error in the use of phenolphthalein as a dilution indicator in gastric analyses. (1) The solubility of phenolphthalein in the acid form, both in water and in dilute alcohol, is considerably lower than the concentration which it is necessary to employ in a test meal. Even if the latter be prepared immediately before it is administered to the subject, in the course of a two hour Rehfuss series determination a considerable amount will be lost by precipitation in the stomach and by filtration of the specimens to remove mucin and other solids preparatory to colorimetry. (2) Phenolphthalein, at a concentration of 10 mgm.

per 100 ml. and a pH of about 12, the lowest pH value compatible with maximum conversion of the indicator to its red salt form, loses color at a significant rate. The second of these errors can be obviated by not alkalinizing the phenolphthalein solutions until just before they are introduced into the colorimeter cups for reading, but the first error constitutes an insurmountable barrier to the use of the substance as a dilution indicator. It follows, therefore, that all previous work based on the use of phenolphthalein in this way involves one or both of these errors unless otherwise demonstrated and should be repeated with the aid of a more reliable substance. To this end we have investigated phenol red. Our results indicate that this indicator possesses neither of the disadvantages of phenolphthalein, since it is soluble in the acid form and the rate of decolorization of the red alkali salt at pH 11-12 is so slow as to be insignificant. A preliminary report of this work has already been published (Hollander, Penner and Saltzman (11)).

The Effect of Ephedrine on the Secretion of Acid by the Human Stomach*

By

M. A. RAFFERTY, Ph.C.

With the assistance of

EDWARD J. VAN LIERE, M.D.

and

CLARK K. SLEETH, B.S.

MORGANTOWN, WEST VIRGINIA

CHEN (1) in 1926 reported that in two dogs with Heidenhain pouches and three with Pavlov fundus pouches, ephedrine given subcutaneously or intravenously increased the gastric secretions both in volume and acidity. This increase was very slight, less in fact, than that after a meal. There was no difference in the two types of pouches. Results of a number of experiments have been reported on the effect of ephedrine on the movements of the stomach *in situ* in animals. These, in general, suggest a relaxation with inhibition of peristalsis (2, 3, 4). Fray (5) made a roentgenological study of the effect of ephedrine upon the human stomach. He observed that ephedrine, in the vast majority of cases, produces a diminution in peristalsis and tone of the stomach free of local disease. Van Liere, Lough and Sleeth (6), in 1936, determined fluoroscopically that ephedrine in therapeutic doses produces a marked prolongation in the emptying time of the healthy human stomach. Hellebrandt (7) reported that a definite relation may be demonstrated between the motor and secretory function of the human stomach. The acidity of the gastric contents increases as the motility augments and subsides with the onset of quiescence. This parallelism persists whether the stomach is in the fasting condition, or under the functionally stimulating influence of food.

In view of these findings and since ephedrine enjoys such a wide usage in medicine it was thought worth while to study its effects on the secretion of acid by the normal human stomach after an Ewald meal.

METHOD

Three healthy young male subjects were used in this work. The normal gastric acidity curves in response to an Ewald meal were determined according to the fractional method.

No food had been taken since the evening before. At 8:00 a. m. the residuum was removed from the stomach by a Rehfuss tube and examined for pus,

distinctly decreased both the total acidity and the free hydrochloric acid of the gastric juice.

In view of these findings, combined with the well established fact that ephedrine in therapeutic doses depresses gastric motility, it is suggested that this drug might find therapeutic application in the treatment of certain selected cases of uncomplicated gastric ulcer.

Vitamin C Nutrition in Pulmonary Tuberculosis*

By

GUSTAV J. MARTIN, Sc.D.†

and

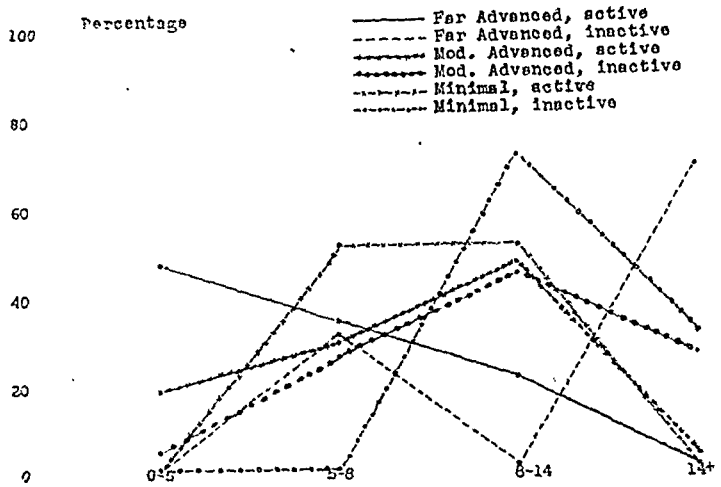
FRED H. HEISE, M.D.‡

TRUDEAU, NEW YORK

THE literature relating to experimental animals indicates a decreased resistance to tuberculous infection in animals on a vitamin C deficient diet (1-8). Mouriquand and co-workers (5), Bieling (6), Heymann (3) and Basu (7) showed that the combination of a partial depletion of vitamin C and progressive tuberculous infection shortened the life of guinea pigs. Greene and co-workers (8) demonstrated clearly the effect of vitamin C deficiency on tuberculosis in guinea pigs. They conclude: "Chronic vitamin C deficiency combined with a progressive tuberculous infection causes a significant shortening of the survival period and a significant decrease in the body weight of guinea pigs." Beiling (4) found that animals with chronic tuberculosis were more easily precipitated into acute scurvy.

The literature dealing with hypervitaminosis C in animal tuberculosis is inconclusive. Leichtentritt (9) gave large amounts of orange juice to tuberculous guinea pigs on normal diets and found the survival period to be twice as long as that of tuberculous animals on the normal diet. Grant (10) reported that increasing the amount of vitamin C seemed to decrease the severity and extent of the tuberculous lesions in the lungs of guinea pigs. Bella (11) noted no increased resistance in tuberculous animals whose diet was supplemented by orange juice and cevitamic acid. Heise and Martin (12) found no protection from the use of cevitamic acid given intravenously over a period of five months. The question of hypervitaminosis C in tuberculosis of experimental animals is by no means settled.

Results obtained from experiments on animals cannot be expected to apply also to human tuberculosis as it is a well known fact that a disease analogous to human tuberculosis has never been produced in experimental animals. Clinical reports (1, 13, 14, 15) have appeared to the effect that scurvy renders a patient increasingly susceptible to tuberculosis, while the addition of vitamin C to the diet improves the prognosis in these cases. Schroeder (16) has reported increased requirement of vitamin C in all diseases accompanied by fever. Three cases of tuberculosis were studied: two for a period of five days during which they were fed 300 mg. of ascorbic acid daily. The report of Bullowa et al (17) shows in one tuberculous patient a reduced excretion of vitamin C but with prolonged dosage of ascorbic acid a high peak was reached which fell rapidly on discontinuing the treatment.



PROCEDURE

One hundred fifty tuberculous patients and fifteen normal non-tuberculous individuals were studied. The state of vitamin C nutrition was determined by collecting 24-hour urine samples, using glacial acetic acid as a preservative, and titrating with 2-6 dichlorophenolindophenol. Tillmanns and associates (18, 19, 20), Harris and associates (21), and Bessey and King (22) have demonstrated the close correlation between vitamin C biological assays and the titration values, using this indicator. All patients and controls were on the regular sanatorium diet. This permits of comparison of individual cases, but the results cannot be compared with those of other workers dealing with uncontrolled basic diet. The test dose method of determining the state of subnutrition as described by Abbasy et al (23) was used in many cases. The test dose of ascorbic acid* was given intravenously in some instances and orally in others, both normal and tuberculous individuals being tested. The extent and activity of the tuberculous process was simultaneously determined by X-ray, sputum examination, sedimentation rates and in some instances by tuberculin skin tests. It is to be emphasized that this study deals with uncomplicated tuberculosis. Exceptions to this will be designated. Any attempt to correlate extent and activity of tuberculous involvement with vitamin C nutrition would be futile in the presence of any complicating diseases. This factor was eliminated in this study by constant observation and routine physical examinations. Evidence of the effect of other diseases on the state of ascorbic acid metabolism is discussed

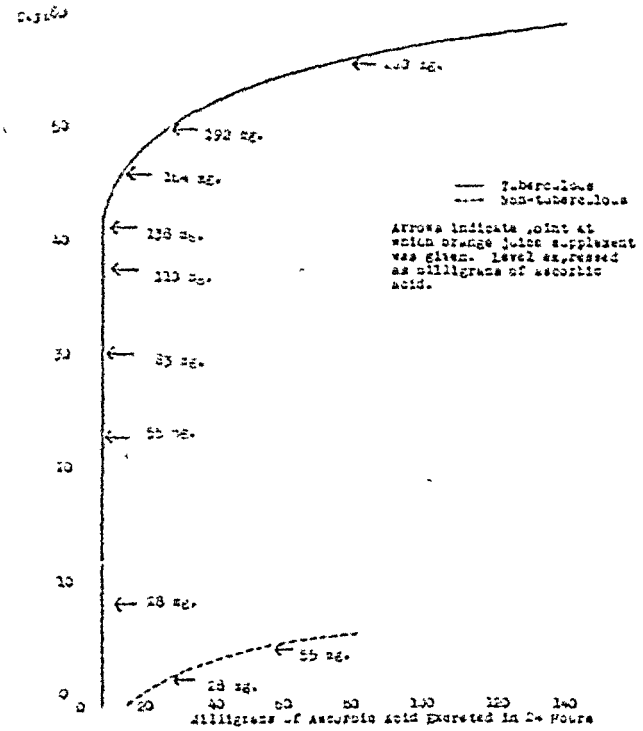
in reviews (23, 24, 25) and is too extensive for discussion here. Urinary pH was checked in all cases, as Hawley et al (26) have shown that alterations in urinary pH have a definite effect on the vitamin C content of the urine. The amount found was less when the reaction was alkaline. Variations in pH were within 1, which eliminates pH as a complicating factor in this work. Selection of cases was made to include inactive and active cases classified as minimal, moderately advanced and far advanced.

The 2-6 dichlorophenol indophenol was standardized every third day against pure crystalline ascorbic acid. Microburettes were used in the titrations. All ascorbic acid given intravenously was the neutralized product.

RESULTS

Excretion of Ascorbic Acid on the Sanatorium Diet; no supplements.



In a study of 116 cases, Table I, 10 normal (non-tuberculous) cases were found to be excreting 14 mg. of ascorbic acid or more daily. Those with tuberculosis fell into four principal groups: (1) in which the daily excretion ranged from 0 to 5 mg.; (2) in which the daily excretion ranged from 5 to 8 mg.; (3) in which the daily excretion ranged from 8 to 14 mg.; (4) and the group in which the daily excretion was 14 mg. or more. Sixteen out of 106 tuberculous cases showed an excretion of over 14 mg. of ascorbic acid in 24 hours. The range here was from 14 to 18 mg., whereas the non-tuberculous control group showed a range from 17 to 44 mg. daily on the same diet. A series of twenty cases was studied to determine the general effect of the sanatorium diet on vitamin C excretion. A determination of ascorbic acid was made when the patient was admitted and again two weeks later. As all twenty of these cases showed, on the second determination, slight increases of from 1 to 3 mg. daily in their vitamin excretion, values for comparison recorded in this paper are exclusively values determined after the patients had been on the sanatorium diet over two weeks. Fifty-four cases judged active by clinical and laboratory findings were studied: 22 of these excreted above 8 mg. of ascorbic acid daily; 1 case excreted above 14 mg. daily. Fifty-two cases judged inactive by the same criteria were studied: 13 of these excreted less than 8 mg. of ascorbic acid daily, and 2 excreted below 5 mg. of ascorbic acid daily. Generally, all cases of pulmonary tuberculosis have a hypovitaminosis C as a complicating factor, and the degree of this hypovitaminosis seems to parallel roughly the extent and activity of tuberculous involvement.

Ten cases of pulmonary tuberculosis with intestinal involvement were studied but failed to show any

feature of ascorbic acid nutrition distinguishing them from patients with no intestinal tuberculosis.

The ascorbic acid excretion of the entire group, 116 cases, was determined on at least two occasions and in some instances followed for five months, determinations being made at biweekly intervals. Determinations made at biweekly intervals on the same patients were found to check within 1 or 2 mg. in 95% of cases. In the ten patients studied over a period of five months, improvement was accompanied by an increased excretion of ascorbic acid. In two of these cases, a sudden decrease in ascorbic acid excretion was noted and when checked by a roentgenological examination both cases were found to have suffered an extention of pulmonary disease and a flare-up in activity.

One hundred thirteen patients were classified in three groups according to the roentgenological findings immediately after determination of the ascorbic acid excretion. First, those whose lesions appeared stationary, of whom there were 46; second, those whose lesions progressed, of whom there were 10; and third, those whose lesions improved, of whom there were 57. In the stationary and improved groups, the majority fell in the groups excreting 8 mg. or more daily,

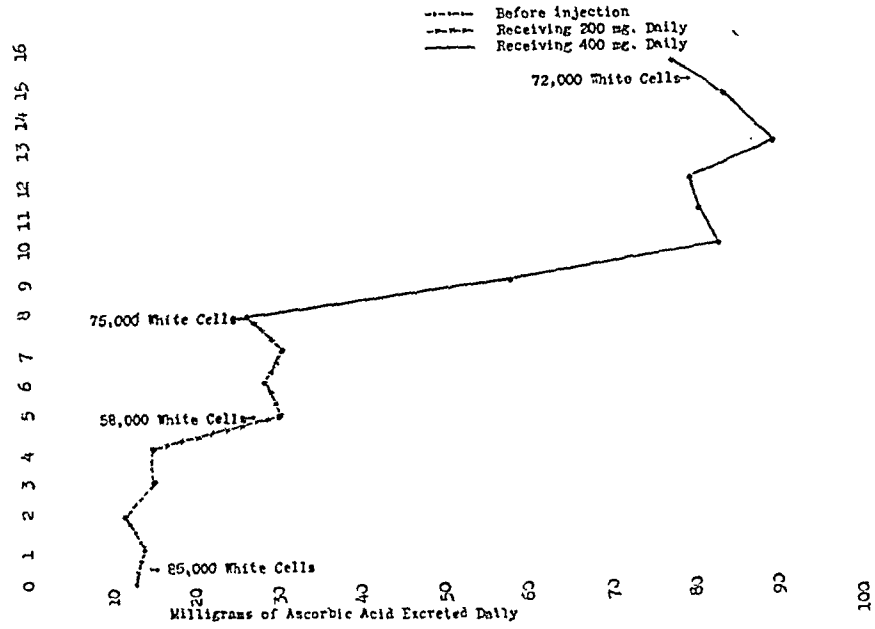
TABLE II

Classification of cases as stationary, improved or retrogressive; subdivided according to ascorbic acid excretion

Ascorbic Acid Excretion, 24 hr. Period	Improved	Stationary	Retrogressive
0-5 mg.	3	5	5
5-8 mg.	15	15	3
8-14 mg.	26	16	2
14 mg. or more	13	10	0
Total Number of Cases	57	46	10

whereas 80% of those whose lesions progressed fell into the groups excreting less than 8 mg. daily. None of those whose lesions progressed fell in the normal group for excretion, whereas 22% of those whose lesions remained stationary were in the group where excretion was 14 mg. or more, and 22% of the improved group had an excretion of 14 mg. or more. Table II clearly shows the parallelism of condition of patients as determined by roentgenological findings and results of ascorbic acid excretion tests.

One hundred patients were classified according to the occurrence of positive or negative sputum at the time of determination of the excretion, and there appeared to be no relation between the quantitative excretion of ascorbic acid and the occurrence of tubercle bacilli in the sputum.



Using the Cutler method, the blood sedimentation rate was determined in 74 patients of whom 51 were males and 23 females. Twenty-seven of the males had a normal sedimentation and 24 an increased sedimentation rate. 37% of those with a normal sedimentation rate likewise had an excretion of 14 mg. or more per day, whereas only 12% of those with high sedimentation rate fell into this group. On the other hand, of those with high sedimentation rate, almost 30% fell in the low excretion group of 0-5 mg., whereas only 4% of those with normal sedimentation rates fell in this group. Of the 23 females, 6 had normal and 17 high

TABLE III

Response of tuberculous patients to a 1 ounce supplement of orange juice (55.2 mg. ascorbic acid) given daily over a period of 2 weeks. A positive response indicates saturation with vitamin C with increased urinary excretion

sedimentation rates. Of those with normal sedimentation rates, 17% had a normal excretion of 14 mg. or more daily, and 50% fell in the groups 0-8 mg. daily. Of those with a high sedimentation rate, none fell in the extremely low (0-5 mg.) excretion group; 29% were in groups of 8 mg. or less of daily excretion, and 12% had a normal excretion of 14 mg. or more daily.

Graph 3. Ascorbic acid excertion in a patient with tuberculosis and myeloid leukemia following intravenous ascorbic acid.

Responses to Supplements of Vitamin C in Patients with Pulmonary Tuberculosis.

Forty-one patients and eight non-tuberculous individuals were given four ounces of orange juice (55.2 mg. of ascorbic acid by titration) daily for two weeks to determine if possible the saturation point. Twenty-one became saturated and 20 remained unsaturated. The eight non-tuberculous persons originally in the 14 mg. or higher group all gave a positive response. Eight patients were originally in the low group of 0-5 mg. excretion daily. Of these, one became saturated and seven did not become saturated. Fifteen were originally in the 5-8 mg. group. Of these, 46% became saturated and 54% did not. Seventeen were in the group of 8-14 mg. excretion daily. Of these, twelve became saturated and five did not. One was originally in the 14 mg. or more group and became saturated. Approximately 50% of patients became saturated after the use of supplements of 4 ounces of orange juice. Of fifteen active cases, only one became saturated, whereas of 26 inactive cases, 20 became saturated. This checks closely with roentgenological findings. The patients who gave no response to a four-ounce supplement of orange juice daily were continued on varying levels of orange juice to determine the daily intake of ascorbic acid necessary to cause it to saturate the body and spill over into the urine. Two non-tuberculous cases were given comparable doses as controls, although they responded to a 2 oz. supplement of orange juice. Table IV and Graph 1 show the required dosage for positive reaction. Patient No. 9268, with far advanced active pulmonary tuberculosis, gave no positive response even when given 220 mg. of ascorbic acid daily in the form of orange juice. The other patients gave positive responses eventually but only after huge dosages. Each dosage level was continued with each patient until no increase in urinary excretion was observed. In two cases a four ounce level of orange juice (55 mg. of ascorbic acid) was continued for four months with no response. This indicates definitely that it is not a matter of unsaturation solely but also of a marked increase in the daily destruction or utilization of ascorbic acid. The daily requirement of vitamin C for a tuberculous patient may safely be put at 110 mg. (about 8 ounces of orange juice). This provides a factor for safety. Negative results in attempts to saturate these patients might be attributed to one of two factors: alterations in intestinal chemistry (absorption mechanisms from the intestinal tract or destruction by bacteria in the intestinal tract) or increased demands for ascorbic acid by the tissues. Intravenous administration of ascorbic acid was next tried. This eliminates any factors of abnormality in the intestinal tract of the patient in pulmonary tuberculosis. Ten patients were given 200 mg. of cebione intravenously daily; seven of these responded positively, and three did not. All were roentgenologically classified as moderately advanced active cases of pulmonary tuberculosis. Comparison of response to a 200 mg. intravenous dosage and a 220 mg. oral dosage of ascorbic acid would indicate an abnormality in the intestinal tract causing destruction of or deficient absorption of ascorbic acid. Patient No. 9379 and Patient No. 9268 both showed a negative reaction to 220 mg. oral dosage of cevitamic acid given over a period of 6 days and 14 days respectively. The presence of patients showing a negative response to intravenous therapy made it imperative to select a level for intravenous dosages which gave no positive

responses when taken orally. As shown in Table IV no positive reaction was noted to the oral administration of 55 mg. of ascorbic acid and therefore 50 mg. was selected as the intravenous dosage. Four patients were tested; each being given 50 mg. of ascorbic acid daily by the intravenous route. Three of these gave a positive reaction excreting on the fifth day over 35 mg. of ascorbic acid; the fourth patient failing to respond. This evidence leads us to believe that two factors are responsible for the subnutrition observed in tuberculars; an increased demand by the tissues and a deficient absorption.

Patients maintained on each level until no further increase in daily ascorbic acid excretion.

One patient under observation with a minimal case of tuberculosis was found to be suffering from myeloid luekemia. To study both the effect on his tuberculosis and on the leukemia, intravenous ascorbic acid therapy was begun A weak positive response was elicited; 30 mg. of ascorbic acid being excreted on 4 days following a 200 mg. intravenous dose. When the dose was raised to 400 mg. daily, the excretion rose to around 80 or 90 mg. daily. The ascorbic acid had no effect on the white count: the original value before treatment was 72,000 and the final value after the injection of 4200 mg. of ascorbic acid was 85,000, as shown in Graph 2. Eufinger and Gaehtgens (27) have reported the treatment of a case of myeloid leukemia in which the white count was brought back to normal and the clinical picture improved by the injection of 2000 mg. of ascorbic acid. It is difficult to explain the discrepancy.

DISCUSSION

No adequately controlled evidence on the effect of ascorbic acid therapy on the course of pulmonary tuberculosis was obtained in this study. The impression gained from the study is that it does improve the prognosis, but no definite evidence for this impression was obtained. Bachstrom in 1734 (Observationes circa scorbutum) noted a relationship of tuberculosis and vitamin C nutrition. He stated that scurvy could be cured by fresh vegetables provided tuberculosis was not a complicating factor. The relationship has been assumed but not definitely established. All reports to date showing favorable effects on prognosis in tuberculosis of vitamin C have been entirely inadequate to prove the contention. A statistical analysis of these papers would clearly demonstrate their inadequacy.

The present study demonstrates the existence of a hypovitaminosis C in a large majority of tuberculous patients; the degree of hypovitaminosis is shown to parallel the extent and activity of the tuberculous process.

The demonstration of the intestinal tract of the tuberculous patient as a factor in this subnutrition would indicate a loss in the specific absorptive powers of the normal gut for ascorbic acid. The intestinal flora might play a part. Stepp and Schroeder (28) have demonstrated a relation of C hypovitaminosis to the bacterial flora of the gut. Strains of bacillus coli and paratyphus B cause almost total destruction of vitamin C in the intestinal tract The tubercle bacillus might act in a similar manner and its presence in varying numbers in the intestinal tract of the tuberculous patient is certain. The extent of swallowing of bacilli laden sputum would be proportional to extent and activity of the disease; a fact in harmony with the parallelism shown in the degree of C hypovitaminosis and in the extent and activity of the disease. Schroeder and Einhauser (29) have suggested three types of hypovitaminosis C: first, due to a lack of vitamin C in the diet; second, due to deficient absorption caused by altered chemistry of the intestinal tract or bacteria; and third, due to increased requirements of vitamin C. The increased pigmentation seen in certain cases of far advanced tuberculosis is another indication of C deficiency.

The successful treatment of certain hemorrhagic diseases by ascorbic acid has led to the treatment of hemorrhage in tuberculosis with vitamin C. Hasselbach (30) reported results of the treatment of 8 cases of hemorrhage from tuberculosis; two did not respond. Cotti and Larizza (31) attribute the decrease in coagulation time caused by ascorbic acid injections to an increase in coagulation ferments. Junghaus (32) used ascorbic acid with success in the treatment of gynecological bleeding. Two reviews (24, 25) adequately cover the papers dealing with the use of

vitamin C in the treatment of hemorrhagic disorders. Our attempts to stop hemorrhage in tuberculosis by the intravenous administration of ascorbic acid were not successful. Eight attempts gave no positive results. Judging from previous experience the conclusion was reached that the period over which the pulmonary hemorrhage extended was in many cases shortened; however, a larger series would be necessary to establish this point. That immune mechanisms are impaired by deficient vitamin C nutrition has been established by Jusatz (33). Dogs on a vitamin C free diet were shown to have a low bacteriacidal power of blood. The precipitin titer was 100X greater after the injection of ascorbic acid into the vitamin C free animals. That the mechanisms of immunity are materially altered by ascorbic acid therapy in tuberculosis is shown by the work of Heise, Martin and Schwartz (34) who observed decreased sensitivity to tuberculin following injection of the vitamin.

Svirbely (35) reports that ascorbic acid in adequate amounts is necessary for the proper utilization of the cortical hormone. His findings apply particularly to the localized concentration of ascorbic acid in the adrenal itself. Tislowitz (36) stresses the relationship of cortical function and vitamin C nutrition. Siwe (37) noted a marked C hypovitaminosis in Addison's disease. These reports in combination with the observations of Siehrs and Miller (38) that vitamin C disappears from the adrenals in 3-6 days (long before symptoms of scurvy develop) leads one to believe that an inadequacy of ascorbic acid might be causing abnormalities in hormone function. Adrenal involvement has long been suggested as a complicating factor in tuberculosis and it would seem that the hypovitaminosis C plays an important part. Four cases of advanced pulmonary tuberculosis (39) treated with cortin (donated by Dr. E. C. Kendall) showed no response; but this does not rule out a possible effect, as ascorbic acid therapy was not instituted at the same time. These patients were far advanced cases of long standing and perhaps not the best patients for a trial. Attempts to study the effect in minimal cases would require large numbers of patients and enormous quantities of the cortical hormone.

It is a well known fact that tuberculous processes in the lung are walled off by fibrous connective tissue. Healing of the tuberculous process is a process of fibrosis. Failure to build up a protective wall around the tubercle is conductive to spreading of the disease. That vitamin C is required for the maintenance of all connective tissues is also well known. Fibroblasts, osteoblasts and odontoblasts undergo atrophy; and their inter-cellular fibroglia and collagin fibrils become degenerate, edematous and hyalinize. Considering these facts, the necessity of maintenance of optimal vitamin C nutrition in tuberculosis is obvious. Ascorbic acid applications have been used successfully to stimulate the formation of granulation tissue and hasten healing of surgical wounds (40). It would seem that in any disease accompanied by fever there is an increased demand for vitamin C; in tuberculosis it is doubly essential to promote fibrosis. Excretion of ascorbic acid, the degree of hypovitaminosis C, is not specific for any one disease. This is demonstrated clearly by the work of Drigalski (41).

It is to be emphasized that this work deals with uncomplicated tuberculosis. Hypovitaminosis C is no more characteristic of tuberculosis than it is of other chronic and many acute diseases. The value of ascorbic acid excretion determinations in the prognosis of tuberculosis rests on the absence of complicating diseases. It is suggested that patients with tuberculosis have a polyhypovitaminosis; and although difficult methods of determining degree of hypovitaminosis have prevented work with the other vitamins, this will doubtless be found true when clinically applicable procedures are developed. The nutritional defect in tuberculosis is multiple but the predominating deficiency is the hypovitaminosis C. The importance of an ample diet has long been recognized as an adjunct to the rest cure of tuberculosis and its importance doubtless lies in increased requirement of tuberculous individuals for all the vitamins. Multiple nutritional deficiency again cannot be claimed as specific of tuberculosis; all chronic diseases and many acute diseases with fever would also show a multiple nutritional deficiency.

SUMMARY

Hypovitaminosis C is the rule among patients with pulmonary tuberculosis. The degree of hypovitaminosis parallels the extent and activity of tuberculous involvement. Two factors were demonstrated as responsible for the hypovitaminosis; first, abnormal chemistry of the intestinal tract, and second, increased requirements by the tissues of vitamin C.

Gastro-Intestinal Symptoms from Cardiovascular Disease*

By

HARRY GAUSS, M.D.†
DENVER, COLORADO

GASTRO-INTESTINAL symptoms may arise from sources outside of the alimentary tract. They may arise from causes within the cardiovascular system.

Abdominal distress is merely an expression of trouble somewhere in the body. It is not an index of the location of the lesion producing the symptoms. The abdomen has been properly called the barometer or the spokesman of the body. It merely tells of trouble. It remains for the physician to locate the trouble, bearing in mind that the responsible organ may be located anywhere in the body.

Elsewhere we have pointed out that gastro-intestinal symptoms may originate in the renal system (1) and within the pelvis (2). It is the purpose of this paper to discuss the relationship of the cardiovascular system to the abdominal symptoms.

There are four cardiovascular diseases that sometimes produce pronounced gastro-intestinal symptoms; namely, coronary disease, congestive heart failure, endocarditis, and arteriosclerosis. The mechanism of the production of the abdominal symptoms is different in each of these disease groups, although the resulting clinical syndromes may resemble each other.

CORONARY DISEASE

Coronary disease produces gastro-intestinal symptoms by reflex mechanism acting through the autonomic and vagus nerves. There are no gross lesions present in the gastro-intestinal tract to explain the symptoms that occur.

The clinical picture that coronary thrombosis produces in the abdomen is extremely variable. It varies from a vague abdominal distress continued over a period of months, to a sudden attack of violent pain simulating a ruptured abdominal viscus.

Coronary disease may mimic any type of acute disease in the upper abdomen, although commonly it tends to produce a symptom-complex that resembles gall bladder disease. In 1928, Riesman (3) pointed out that acute coronary obstruction may simulate biliary colic, perforation of a peptic ulcer, acute pancreatitis, or intestinal obstruction; while a nonobliterative endarteritis is also capable of producing digestive symptoms but in a milder degree. In the latter type of case the outstanding symptoms are fatigability on slight exertion, shortness of breath, a sense of oppression in the precordial region or in the epigastrium, and frequently distension with gas. It is the last symptom that often dominates the clinical picture and gives the impression of a primary gastric disease. Riesman however cautions that it is possible for both digestive and myocardial disease to be present at the same time.

Katzman (4) has pointed out that the abdominal symptom-complex resulting from coronary thrombosis is commonly considered by the laity to be a form of acute indigestion, and that the majority of deaths reported in the newspapers as "acute indigestion" are really cases of coronary thrombosis.

Coronary thrombosis may mimic biliary colic so closely, that it requires careful analysis to differentiate the two conditions. In considering the differential diagnosis between these diseases, the following signs and symptoms are mentioned as diagnostic of biliary colic: severe pain in the right upper quadrant of the abdomen which may radiate to the back, nausea and vomiting, jaundice, a slight elevation of the temperature, a slow or a normal pulse rate, the heart tones remain strong, there is no pericardial friction rub, there are no characteristic alterations in the electrocardiographic tracing from day to day; whereas in coronary thrombosis the following signs and symptoms may be present: severe pain in the upper abdomen accompanied by considerable shock, the pain does not radiate to the back, it may, however, radiate to the epigastrium or to the substernal region, it is crampy and paroxysmal, there is marked dyspnoea, nausea and vomiting may occur, jaundice is rare, there is some elevation of the temperature, the pulse becomes rapid, the heart tones are distant, a pericardial friction rub may be present or may develop, the blood pressure

*Read before the Medical Society of the City and County of Denver, March 2, 1937.
†Department of Medicine, University of Colorado.
Submitted April 1, 1937.

drops from 20 to 50 mm., the electrocardiographic tracing may show a high take-off of the T wave as well as a cove shaped inversion, also there may be a sudden shift of the electrical axis, furthermore there may occur a variation in the electrocardiographic tracing from day to day with a gradual falling of the high take-off of the T wave, the attack usually follows a combination of severe mental anxiety and excessive physical effort on part of the patient, although several hours may elapse between the physical strain and the coronary attack.

In addition to those cases of coronary disease where the onset is sudden and dramatic, there are other cases where the symptoms are less violent, where the onset is gradual, where the course is milder, and where the differential diagnosis is much more difficult to make.

Obviously not all cases of coronary disease effect a dramatic onset either thoracic or abdominal. Common sense dictates that for every case of coronary disease that terminates in a thrombosis, there must be many more cases that remain in the nonobliterative stage; also there are those cases where the process of thrombosis and infarction is quite slow in developing; consequently there must be many more patients with mild coronary symptoms than patients with drastic symptoms.

White (5) has pointed out that coronary disease occurs in a large percentage of patients with heart ailments. He states that in a study made in New England, 37 per cent of a series of 2,314 patients with organic heart disease were found to have some degree of coronary involvement. White considers that infarct-producing and clinically recognizable coronary thrombosis is but a single phase of coronary disease, although a striking one.

In the nonobliterative type of coronary disease, the abdominal symptoms do not always present clear cut syndromes. Often they may be vague, or they may mimic any of the common types of gastro-intestinal disorders, while at other times they conform to no known type of gastro-intestinal syndrome. When the patient presents this stage of the disease, it may be quite difficult to differentiate the mild coronary syndrome from the gall bladder dyspepsia. However the *clinical* course of the patient sometimes suggests the possibility of the underlying cause being located elsewhere than in the gastro-intestinal tract, when the patient fails to respond to gall bladder therapy.

Another type of overlapping of coronary and digestive symptoms occurs where there are signs and symptoms pointing to both diseases. Thus a patient complains of fulness in the epigastrium after meals, attacks of pain in the gall bladder region which radiate to the scapula, periods of mild jaundice and clay colored stools, and then subsequently develops precordial pain, cyanosis and shock. In this instance there is likely to be present both diseases. There is nothing unusual in the thought that both diseases may coexist in the same individual. On the contrary it is to be anticipated, since both diseases occur in the same age groups as well as in the same type of constitutional habitus.

In discussing the differential diagnosis between coronary and gall bladder disease, we have not stressed the use of the gall bladder dye test. In a few instances where we have seen the dye test made in the presence of coronary disease, there occurred such violent reactions after the ingestion of the dye, that we have discontinued the dye test in the cases of possible coronary involvement.

The following case reports illustrate some instances of digestive syndromes which apparently originated in the coronary arteries.

Case I. Gall Bladder Dyspepsia Syndrome from Coronary Thrombosis with Recovery.

D. F. H., a physician, 45 years old, 5 feet 10 inches in height, weighing 170 pounds, is a veteran of the world war. He believes and practices the out door life. He is a golfer and a mountaineer. He has always prided himself in his splendid physical condition. He believes that at his age he can play 36 holes of golf or climb a mountain with the vigor of his youth.

D. F. H. began to develop vague abdominal symptoms. At first he noticed a fulness after meals, later he was annoyed with belching and flatulence, then he developed spastic constipation. He had been working hard and worrying over an economic situation over which he had no control. He thought that he was growing flabby, so he increased his physical exercise. The digestive symptoms, however, did not subside. On the contrary they were becoming more annoying. The epigastric fulness after meals grew very distressing, necessitating the loosening of his clothing. He considered the symptoms the result of a gall bladder dyspepsia and accordingly placed himself on a restricted diet and bile salts with pancreatin therapy. However he did not improve. He grew steadily worse for several months, also he noticed increased fatigability and some shortness of breath. He continued with his program of physical exercise. One Sunday afternoon while climbing over his favorite mountain he found a large sized rock that he thought would add to the appearance of his rock garden. He proceeded to haul it on his shoulders to his car. He retired early that evening because of fatigue. At 6 a. m. the following morning, he was suddenly awakened with a terrific agonizing attack of pain under the sternum. He had a horrible sensation of choking and inability to catch his breath. A sensation of impending death oppressed him. The pain radiated down both arms. The agonizing pain continued for about half an hour and then gradually subsided.

When seen several hours later he was ashen-white in color, an obviously sick man. The heart was slightly enlarged, the mitral first sound was weak and indistinct. The blood pressure was 110-55, a fall of 25 mm. from a recent test. The pulse was rapid with a rate of 110 per minute, the temperature was 99.4. There were no abdominal signs or symptoms at this time. An electrographic tracing shows inverted T waves of the Pardee type in lead I.

A diagnosis was made of Coronary Thrombosis.

The patient was put to bed for six weeks. He was placed on a maintenance diet and given theobromine gr. 5 and phenolbarbital gr. ½ after meals. After the first day he became free from symptoms. At the end of six weeks, he was placed on a controlled program of exercise and subsequently returned to his practice.

Comment. Patient D. F. H. presented a digestive syndrome as an expression of coronary disease. The coronary disease probably resulted from the combined physical and mental stress in a high tension individual. The patient continued to have digestive symptoms as long as the coronary disease was of the nonobliterative type. The symptoms imitated gall bladder dyspepsia. Treatment for the gall bladder dyspepsia did not relieve the symptoms. Later the patient developed a typical attack of coronary thrombosis and the diagnosis became evident. When the patient was placed on treatment for the coronary lesion, the digestive symptoms subsided.

Case II. Gall Bladder Disease Syndrome from Coronary Thrombosis with Recovery.

B. M., age 60, is a self made man, and a successful one. He "arrived" by hard work. At the age of 60 he is a successful banker and still works hard, too hard for a man of his age. For several years he has been under a mental strain by reason of rumors of inflation of the currency. Recently he had purchased a ranch where he had hoped to spend his declining years. He started to get acquainted with his ranch by pitching hay and chopping away some underbrush.

B. M. is 5 feet 2 inches in height and weighs 135 pounds. He has always enjoyed robust vigorous health. However, about November 2, he began to experience a disagreeable sensation under his right hypochondrium. Then the pain became sharp and boring, and radiated to the epigastrium. He also complained of fulness after meals, flatulence, gas eructations, some shortness of breath and some loss of strength. The syndrome pointed to a gall bladder dyspepsia, and arrangements were made to study the gall bladder roentgenologically. The patient, however, wished to delay the examination in order to make the necessary arrangements for absenting himself. On the evening of Nov. 12, he had a sudden attack of excruciating pain in the precordium which radiated down both arms.

When he was seen about an hour later he was still having the agonizing distress. He appeared cyanotic, cold, and clammy. His pulse was rapid, the mitral first sound was weak and distant. He had not taken the gall bladder dye. He was given a quarter grain of morphine, brought to the hospital, put to bed at absolute rest, and given theobromine gr. 5 and phenolbarbital gr. ½, three times daily and placed on a light diet. The next day his temperature was 101.4, the pulse 110, the respiration 20, the blood pressure 110/56 which was a decrease in the systolic pressure of 50 mm. from a week previously. The leucocyte count was 14,200. The electrocardiographic tracing shows inverted cove shaped T waves in lead III with a high take-off; in lead III there are also deep Q waves; in lead II there is a beginning inversion of the T waves.

A diagnosis of Coronary Thrombosis was made. The patient was kept in bed for six weeks, and then allowed to resume some of his activities slowly. After the second day in bed he became symptom free from both the thoracic as well as the abdominal symptoms.

Comment. Patient B. M. presented the syndrome of gall bladder dyspepsia as an expression of coronary disease. This continued for several days when a typical attack of coronary thrombosis appeared, which was confirmed by the electrocardiographic studies. The digestive symptoms subsided under treatment for the coronary disease.

Case III. Gall Bladder Disease Syndrome from Fatal Coronary Thrombosis.

A. G. was an attorney, a successful trial lawyer, one of those high-pressure dynamic personalities. He was trying a case in the district court that had attracted considerable attention. The case had reached the stage where on the following day he would make his final plea to the jury. If the jury rendered a favorable verdict for his client, the case meant much to him.

A. G. was a big strapping fellow of 50 years, he was 5 feet 11 inches in height and weighed 210 pounds. He had married recently and was greatly in love with his young wife.

On the morning of March 4, the day preceding his final plea to the jury, he awoke feeling nervous and tired, and somewhat pale in color. He attributed these symptoms to his anxiety over the outcome of the trial. Later in the day, after lunch, he had an attack of "acute indigestion," a sudden sensation of distress in the epigastrium with fulness and distention. The pain was quite severe. He felt nauseated, vomited, and felt somewhat relieved, but still weak. He took several aspirin tablets, and the distress eased up some, sufficient to permit him to make his way to the physician's office.

The syndrome presented by the patient at the time suggested an attack of gall bladder disease, so the patient was advised to go to a hospital immediately for observation and treatment.

A. G., however, would not enter a hospital on that day. He had that important address to make to the jury on the following day. He wanted his physician to give him a little something to fix him up for the remainder of the trial, after which he might enter the hospital. The physician again urged him to enter a hospital immediately and postpone his trial, all to no avail. He left the physician's office, went home, and died suddenly several hours later.

A postmortem showed a coronary thrombosis of the left coronary artery, a left ventricular hypertrophy, some generalized arteriosclerosis. The gall bladder was normal.

Comment. Patient A. G. presented a syndrome of digestive symptoms suggestive of a gall bladder syndrome as an expression of coronary disease. He died several hours later from a coronary thrombosis, which was confirmed by postmortem examination.

Case IV. Fatal Coronary Thrombosis with Gall Stone Obstruction.

E. W. K., age 66, was a mining engineer, who plied his trade with a youthful vigor. He had hardly known a sick day in his life. He was one of those men who had little use for "sissies," and had no time to be sick himself.

On Feb. 1, he was inspecting a mine up in Cripple Creek at an elevation of 10,000 feet. That noon he ate a heavy meal which contained excessive grease; about a half hour later he had an attack of "acute indigestion," with severe pain in the right hypochondrium and epigastrium. The pain radiated to the back. At first the pain was slight, then it grew steadily worse. The pain spread to the precordium and down both arms. He felt a sense of pressure about the heart, and he became short of breath.

There was no physician conveniently accessible at the time, so he sought relief by taking some soda, and felt better for a few minutes. Then the pain returned and with it he felt nauseated, so he took some ipecac, vomited, and felt considerably relieved. His temperature was taken by a mine superintendent and found to be 97, his pulse was 40. Mining men have a fear of contracting pneumonia in the higher altitudes, so he decided to get to a lower altitude as quickly as possible. The next day he came to Denver and was examined on Monday, Feb. 2. He recalled that he had been slightly jaundiced for several days, and that his stools had been clay colored.

Examination showed a well nourished man weighing 180 pounds, measuring 5 feet 10 inches in height. He was markedly dyspnoeic and short of breath, the temperature was 97 and the pulse was 55, the respiration was 20, the blood pressure was 116/62. The heart was slightly enlarged transversely, the mitral first sound was weak and distant. There was a definite tenderness in the gall bladder region, the lower border of the liver was palpable and tender. The urine contained bile, a trace of albumin, some casts. The white blood count was 15,200.

A diagnosis was made of Gall Stone Colic with Coronary Disease, and immediate hospitalization urged.

E. W. K. left the office to go to the hospital, but stopped at the hotel to gather up some luggage. While in his room, he had another attack of pain and died suddenly.

A postmortem examination showed a coronary thrombosis of the left coronary artery, generalized arteriosclerosis, left ventricular hypertrophy, a contracted thickened gall bladder containing some gall stones, a small stone in the common duct, jaundice, atherosclerosis of the aorta, etc.

Comment. Patient E. W. K. presented a syndrome pointing to both coronary disease and gall stone colic. A postmortem examination established the existence of both diseases.

CONGESTIVE HEART FAILURE

Congestive heart failure is a common cause of gastro-intestinal symptoms.

The mechanism of the production of symptoms is quite different from that in coronary thrombosis. Whereas coronary disease is considered to act on the gastro-intestinal tract by reflex mechanism through the autonomic and vagus nerves, or through the altered flow and resulting changes in nutrition, congestive heart failure produces organic changes in the abdominal viscera. These alterations in addition to the impaired nutrition resulting from the diminished blood flow are responsible for the abdominal symptoms.

The pathologic manifestations of congestive heart failure are extremely variable. The following lesions occur commonly: hypertrophy and dilation of the heart, coronary sclerosis, myocardial fibrosis, stasis of the portal circulation, stasis of the pulmonary circulation, and their diverse manifestations.

It is the portal stasis that is largely responsible for the digestive symptoms in congestive heart failure.

The rapidity of the development of the congestive heart failure determines the severity of the symptoms. Rapid engorgement of the liver may simulate acute disease of the upper abdomen, and may mimic acute gall bladder disease very closely. Wedd (7) has pointed out that in rapidly developing congestive heart failure, the liver acts as a reservoir for the blood, as a result of which it engorges rapidly. The hepatic capsule becomes suddenly distended, which results in acute pain in the upper abdomen, accompanied by distension, nausea and vomiting. This syndrome may mimic acute gall bladder disease, and had led to the performance of laparotomies that had better been left undone. He recites an instance where a laparotomy was performed for a supposed gall bladder disease, in which the gall bladder was found to be normal. Later it developed that the symptoms had been caused by engorgement of the liver due to congestive heart failure from auricular fibrillation.

The following case report illustrates a patient who presented pronounced gastro-intestinal symptoms from congestive failure due to mitral stenosis.

Case V. Acute Abdominal Pain from Congestive Heart Failure due to Mitral Stenosis.

Mrs. S. H., a housewife, complains of a sharp pain in the epigastrium which has persisted for three days. The pain appeared suddenly after the eating of a heavy meal. The pain has become constant. It is a boring, pressing pain, accompanied by a sensation of fulness and distension of the upper abdomen. The pain is aggravated by muscular effort. The patient also complains of considerable flatulence and constipation. There is some swelling of the ankles and some shortness of breath.

The writer saw this patient through the courtesy of Dr. Katzman of Denver.

Physical examination shows a well nourished woman, 56 years old, weighing 130 pounds and measuring 4 feet 10 inches in height. She is somewhat pale and dyspnoeic in appearance. The pulse rate is 96 per minute. The blood pressure is 150/90. The heart is enlarged 5 cm. to the left. A presystolic murmur is heard at the apex which is transmitted to the axilla.

The liver is enlarged and extends 8 cm. below the costal margin. It is palpable and tender. The muscles in the right upper quadrant of the abdomen are slightly tense and spastic. The abdomen is distended and tympanitic. The ankles are swollen. The bases of the lungs are dull and contain some moist rales.

A diagnosis was made of Mitral Stenosis and Congestive Heart Failure.

The patient was put to bed, given digitalis in adequate doses, and placed on a light diet.

Within a few days, the abdominal pain subsided, the liver receded, and the abdominal distention disappeared. The shortness of breath, however, continued for some time, but later it responded to continued treatment.

Comment. Patient S. H. presented a syndrome of acute abdominal pain, flatulence and abdominal distention as an expression of congestive heart failure due to mitral stenosis. The pain probably resulted from the sudden engorgement of the liver, which was found to be enlarged at the time of examination. When the patient was placed on treatment for the heart lesion, the digestive symptoms subsided.

ENDOCARDITIS

Like congestive heart failure, endocarditis causes digestive symptoms primarily by producing changes in the abdominal viscera.

The essential mechanism in the production of the symptoms consists in the formation of emboli which lodge in the spleen producing infarcts.

The spleen, next to the kidneys, is the commonest site of infarction from endocarditis either subacute or chronic. The resulting infarct is usually anemic in appearance, wedge shaped, yellowish white in color, bordered by an inflammatory zone. Multiple infarcts are common. Infarction of the entire spleen may occur. Nuzum (6) reports a case of massive infarction of the entire spleen due to an embolus from a mitral endocarditis which lodged in the splenic artery. The spleen was "a soft yellow necrotic mass not normal at any point."

The resulting symptoms are quite variable. They may be violent and simulate a ruptured viscus, the symptoms may be milder, or there may be a minimum of symptoms. Commonly there occurs a sharp attack of pain in the splenic region, accompanied by rigidity of the muscles in the left upper quadrant of the abdomen. At other times there is present a dull bearing down pain, and at other times no pain at all. The pain when present is aggravated by deep inspiration. Nausea and vomiting may occur. The spleen enlarges, becomes palpable and tender. A localized friction rub may appear which is an expression of a localized peritonitis. Fever occurs if the emboli contain bacteria which set up a local infection in the spleen which may then pass on to abscess formation. Nuzum states that vomiting of blood is of frequent occurrence; the blood may be bright or coffee ground in color.

The syndrome may simulate a ruptured abdominal viscus. This has been observed by Wedd (7) who states that "a primary cardiac disease which I have found to have significance for the surgeon is subacute bacterial endocarditis . . . . . Abdominal symptoms resulting from infarction of the spleen and perisplenitis occurring in subacute bacterial endocarditis have been observed, and three patients in whom laparotomies were performed have been recorded."

Infarction of the spleen may terminate fatally. This is apt to occur in subacute bacterial endocarditis

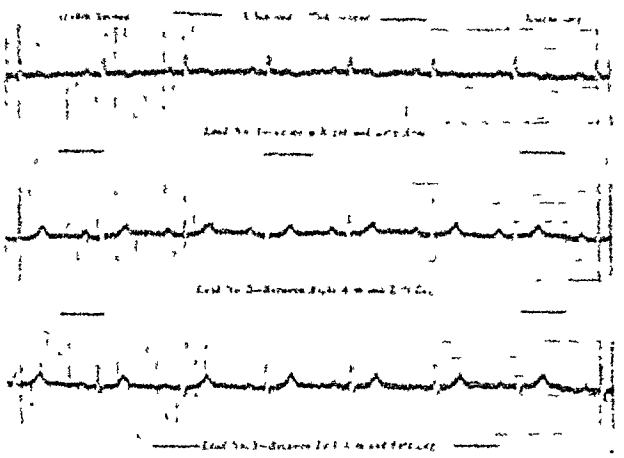

Fig. 1. Electrocardiographic tracing of patient D. F. H. having inverted T waves of the Pardee type in lead I.

where as a result of the bacterial emboli, the infarcts become infected. The infected infarcted area passes on to abscess formation, Peritonitis and death follow.

Vallee (8) reports such a case. His patient entered the Hotel Dieu Hospital of Quebec with cardiorenal disease. Examination showed evidence of both subacute bacterial endocarditis and chronic endocarditis of the mitral and aortic valves as well as renal insufficiency. The patient's course was without appreciable change from July to September when his temperature became elevated and irregular and he complained of acute pain in the left hypochondrium which he described as intolerable. The pain did not remain constant. It shifted to the right side, then disappeared, then reappeared again in the left upper quadrant with increasing severity. It continued in this shifting manner for four to five days, when the patient passed into coma and died. Postmortem examination showed peritonitis, chronic vegetative endocarditis of the aortic and mitral valves. The spleen was covered with a purulent exudate, and contained multiple infarcts, one of which was large, typically wedge shaped, pale in appearance and apparently several days old. The smaller infarcts were in various states of degeneration. There were multiple ruptures in the spleen, which Vallee believes resulted from a necrosis through the capsule as a result of the abscess formation which took place in the infected infarcts.

ARTERIOSCLEROSIS

Arteriosclerosis produces gastro-intestinal symptoms by causing organic changes in the abdominal blood vessels supplying the digestive tract.

Two stages of the resulting digestive syndrome occur, an early stage and a late one. In the early stage of the disease, the patient presents general dyspeptic symptoms as belching, flatulence, epigastric fullness after meals, constipation, heartburn, headache, biliousness. These symptoms are caused by an impaired functional activity of the digestive viscera due to a chronic bad blood supply and impaired nutrition, which compels the digestive viscera to work under stress.

At this stage, the digestive syndrome seldom imitates any abdominal disease. It is easily recognized for the functional disorder that it represents. It presents no problem in diagnosis. Therapeutically it usually responds satisfactorily to dietetic restriction, digestive and sedative therapy.

In the late stage of the syndrome, the patient develops attacks of violent pain in the abdomen. The pain is sharp and paroxysmal, sudden in appearance. It may locate anywhere in the abdomen, although commonly it centers in the epigastrium or the umbilical region.

At this stage, the syndrome may mimic gall bladder colic, renal colic, lead poisoning, tabetic crisis, or other types of acute abdominal disease. The underlying pathologic lesion for this sharp colicky pain is a marked sclerosis of the mesenteric arteries. These are markedly thickened, rigid, sclerotic, pipe-stem in character with diminished lumens.

This syndrome resulting from arteriosclerosis of the abdominal arteries supplying the digestive tract has also been designated as "angina abdominalis." Elsewhere (9) we have discussed this syndrome in detail. The term was introduced by Bacelli in 1897. The writer regards the term "angina abdominalis" as synonymous with the digestive syndrome occurring in cardiovascular disease resulting from a marked sclerosis of the abdominal arteries supplying the digestive tract.

The outstanding symptom is the pain. It occurs as a sharp paroxysmal pain, sudden in appearance, lasting from a few minutes to several hours, and it tends to occur two to three hours after the taking of food. It is commonly associated with general weakness, loss of weight, secondary anemia, distention, flatulence, biliousness. Our patients have described the pain as horribly severe and agonizing, the dread of which made their life a burden, and from which they would welcome permanent relief. Several patients required morphine for the relief of the pain.

Sometimes the pain becomes dull and continuous in character. The patient complains of a dull ache, soreness and sometimes a throbbing in the abdomen. At this stage the syndrome may simulate malignant disease of the abdomen.

Gilbride (10) has reported a series of four patients with arteriosclerosis who were suspected of having malignant disease by reason of their symptoms. In the case report (9) that the writer discussed under "Angina Abdominalis," patient L. B. M. had been sus-

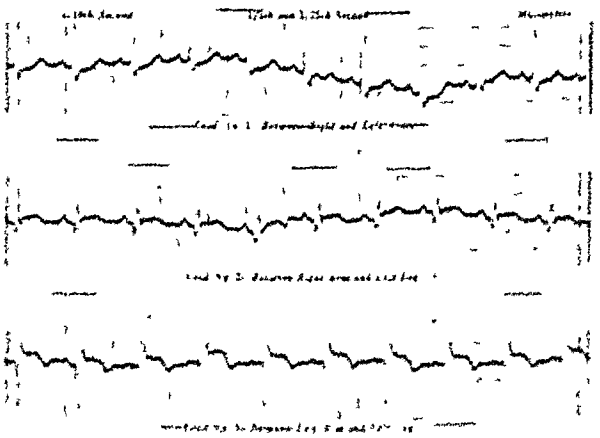

Fig. 2. Electrocardiographic tracing of patient B. M. showing inverted cove shaped T waves in lead III with a high takeoff, deep Q waves in lead III, and a beginning inversion of the T waves in lead II.

pected of having a carcinoma of the pancreas; and at one time had been admitted to a hospital with this diagnosis. The diagnosis of arteriosclerosis of the abdominal arteries supplying the digestive tract was subsequently confirmed by a postmortem examination. There was no malignancy present.

Regarding the nature of the abdominal pain in these patients, Ortner (11) believes that as a result of the marked arteriosclerosis of the mesenteric arteries, the intestines do not receive a sufficient quantity of blood, the intestinal walls become poorly nourished and are incompetent to perform their work efficiently. This becomes manifest several hours after the ingestion of food when the intestines take up their phase of the digestive cycle. Under the burden of this strained physiologic function due to the diminished blood supply, the visceral pain appears.

Regarding the question of whether it is possible for viscera to produce pain, Sir James MacKenzie (12) has stated that pain is a function peculiar to the cerebrospinal nervous system as distinct from the autonomic; nevertheless it is known that pain does arise from viscera. In this case the pain is referred to the distribution of the sensory nerves in the external wall and not to the viscera that initiate the impulses. There is only one demonstrable cause for visceral pain, and that is a contraction of muscle rendered anoxemic by insufficient blood supply. According to this view, an intestine which is engaged in its phase of the digestive cycle, will give rise to pain if its blood supply is deficient. Such is the case in marked arteriosclerosis of the mesenteric blood vessels, where the lumens of the vessels have been reduced in size.

Case VII. Gastro-intestinal Syndrome from Arteriosclerosis, so-called "Angina Abdominalis."

S. R., age 60, had been a retired merchant, and lived off the income of his real estate. He had enjoyed reasonably good health up to the time of the depression when he lost practically all of his property and was reduced to the necessity of living as a pensioner on a friend's bounty, when he began to fail in health and developed digestive symptoms.

He complained of abdominal pain after meals, coming on about two hours after the ingestion of food, also flatulence, belching, constipation, loss of weight, progressive weakness. In the past year he lost about fifteen pounds.

When he was first seen in August, 1934, his presenting symptom was abdominal pain. Although it had begun as a mild discomfort, it had increased in severity, so that he had sought relief from it. At first he obtained relief by lying down, restricting his diet, or taking soda. Later these had failed to give him relief. He restricted his diet still more, but still was unable to get the desired relief. He began to fear meal time, knowing the discomfort that followed.

S. R. was 5 feet 4 inches in height, weighed 135 pounds, he was pale and anemic in appearance, sallow in color. The blood pressure was 176/82. The heart was enlarged to the left, the aortic second sound was accentuated, the pulse was irregular with occasional dropped beats. The radial arteries were hardened and sclerotic. The eye grounds showed arteriosclerotic changes. An X-ray examination of the gastro-intestinal tract showed some spasticity of the colon with delayed emptying time. An Ewald test meal indicated a hypoacidity, the blood showed a secondary anemia. The stool was free from occult blood.

A diagnosis was made of Arteriosclerosis with Digestive Syndrome, so-called "Angina Abdominalis," Spastic Colon, Hypoacidity, Secondary Anemia.

The patient was placed under symptomatic treatment consisting of a maintenance diet given as frequent small meals, pancreatic extract with bile salts, theobromine with phenolbarbital and prescribed hours of rest. Nevertheless under treatment he continued to grow worse. The abdominal pain became sharp, paroxysmal and agonizing and required morphine for control. The patient lost weight, became emaciated, and developed a marked arrhythmia. The anemia increased, and he died following an attack of abdominal pain.

A postmortem examination showed generalized arteriosclerosis, some enlargement of the left ventricle, atherosclerosis of the aorta and coronary arteries. Of special interest were the mesenteric arteries which were hard, firm, brittle, sclerotic, pipe-stem in character with markedly reduced lumens.

SUMMARY

1. Gastro-intestinal symptoms may arise from lesions outside the gastro-intestinal tract.

2. They may arise from causes within the cardiovascular system.

3. There are four cardiovascular diseases that produce pronounced gastro-intestinal symptoms at times, namely: coronary disease, congestive heart failure, endocarditis, and arteriosclerosis.

4. Each of these four cardiovascular disease groups produces the abdominal symptoms in its own characteristic manner, although the resulting abdominal syndromes may resemble each other.

5. Coronary disease produces gastro-intestinal symptoms by reflex mechanism through the vagus and autonomic nerves, as well as through the altered blood flow and the resulting impaired nutrition.

Coronary disease sometimes simulates acute gall bladder disease. It is the fatal "acute indigestion" of newspaper accounts.

6. Congestive heart failure causes gastro-intestinal symptoms by producing organic changes in the abdominal viscera as hepatic engorgement and enlargement, portal stasis, etc. Sudden distention of the hepatic capsule is believed to account for the acute abdominal pain in congestive heart failure.

7. Endocarditis causes digestion syndromes by producing organic changes in the abdominal viscera. The essential mechanism consists in the formation of emboli which lodge in the spleen, producing infarcts.

8. Arteriosclerosis causes digestive symptoms by producing organic changes in the abdominal blood vessels supplying the digestive tract. The late stage of this syndrome has been designated as "Angina Abdominalis." It is characterized by a sharp agonizing paroxysmal pain coming on several hours after eating.

The mechanism of this pain is believed to be based on the impaired blood supply to the intestines due to diminution in the lumens of the mesenteric arteries. When the intestines are forced to labor under deficient blood supply, pain results.

9. Cardiovascular disease may mimic any type of acute abdominal disease although the following syndromes are commonly suggested: acute gall bladder disease, chronic gall bladder dyspepsia, ruptured abdominal viscus, renal colic, lead colic, and malignancy.

10. There are no pathogonomic gastro-intestinal symptoms of cardiovascular origin.

11. The differential diagnosis between cardiovascular and digestive disease is arrived at by a careful consideration of both systems aided by the electrocardiographic tracing of the heart which may show

pected of having a carcinoma of the pancreas; and at one time had been admitted to a hospital with this diagnosis. The diagnosis of arteriosclerosis of the abdominal arteries supplying the digestive tract was subsequently confirmed by a postmortem examination. There was no malignancy present.

Regarding the nature of the abdominal pain in these patients, Ortner (11) believes that as a result of the marked arteriosclerosis of the mesenteric arteries, the intestines do not receive a sufficient quantity of blood, the intestinal walls become poorly nourished and are incompetent to perform their work efficiently. This becomes manifest several hours after the ingestion of food when the intestines take up their phase of the digestive cycle. Under the burden of this strained physiologic function due to the diminished blood supply, the visceral pain appears.

Regarding the question of whether it is possible for viscera to produce pain, Sir James MacKenzie (12) has stated that pain is a function peculiar to the cerebrospinal nervous system as distinct from the autonomic; nevertheless it is known that pain does arise from viscera. In this case the pain is referred to the distribution of the sensory nerves in the external wall and not to the viscera that initiate the impulses. There is only one demonstrable cause for visceral pain, and that is a contraction of muscle rendered anoxemic by insufficient blood supply. Von Bergmann does not frequently find diabetes due to overfeeding, as Joslin stresses with so much vigor. Yet he is also not inclined to look upon every obesity as an endogene one, and he finds transition forms from obesity due to overfeeding and laziness to the so-called endogene obesity. Von Bergmann does not think that obesity occurs with a special frequency in certain families and races, with which habits of food and cooking are hereditary, and he also contradicts the assumption that diabetes and obesity are linked together in many families in a hereditary-biological sense.

He places in the forefront, on the contrary, a special "lipomatous tendency," fastened to the tissue itself, and he attempts to show a hereditary disposition towards a disturbance of the carbohydrate metabolism, which, on the one hand, may lead to diabetes, on the other to obesity. This theory also may be acknowledged as a support for the necessity of prophylaxis of diabetes. V. Bergmann thinks that in the obese organism the way from carbohydrate glycogen to the transformation into fat may be made with more facility, and on the other hand the breakdown of the fat tissue by way of the ketone bodies is more difficult. It is also a characteristic feature of obesity that little glycogen is stored in the liver, the carbohydrate more easily flowing to the fat tissue, being gotten there more easily and converted into fat. Increased glycogenolysis, as found by the school of Bergmann besides diabetes in obesity too, is in no respect a diabetic metabolic disturbance. Such a disturbance of glycogen fixation is said to be able to lead to true diabetes. As long as the obese organism has the faculty to store the non-combusted amounts of carbohydrate in its fat tissue, so long is the second, the periphery factor of diabetes absent. If, however, it is no longer able to store the whole amount of carbohydrate, flowing to the fat tissue, it would yet transform only a part of it into fat. The remaining carbohydrate in this case would not be utilized any more. Glycogenolysis persisting, hyperglycemia and glycosuria must occur. In the obese person a true diabetes would become manifest.

The importance of the hereditary and the exogene factor are, consequently, quite differently appreciated by every investigator. None of them has any doubt that diabetes is a disease chiefly originating from a hereditary disposition. According to Umber, however, occurrence and character are fixed by hereditary disposition. The inheritance determines whether there is a mild or a severe form. Environmental influences are able to have some effect upon the course of the disease, not, however, upon its character. According to this view the power of heredity is the punctum saliens. In contrast to this rigid view, Joslin's opinion gains new followers, according to which exogene factors, in addition to the hereditary ones play an important rôle, among them chiefly obesity due to overfeeding.

While these very divergent views prevail there are also different views in regard to the possibility of an effective prophylaxis of diabetes. According to the view of the orthodox disciples of the Mendelian theory the recessive disposition is unavoidably transferred to the descendants. "According to the intensity of the hereditary disposition the manifestation of the disease occurs in an earlier or higher age" (Umber). The school of Joslin hopes to prevent the outbreak of the disease by favorable environmental influences. This conflict of views shows that we are still far removed from a deeper knowledge of the hereditary influences. We must keep in mind that it has not been possible hitherto to uncover the secrets of heredity. We therefore agree with Pannhorst that we are still in the dark about the hereditary factor itself, about the laws governing it and its dependencies, about its penetrance and its expressivity.

It would, however, be of great importance for the prophylaxis if it would be possible to influence the gene, the hypothetical carrier of the inheritance. But there is no hope of solving the problem of heredity by starting from the gene. Development is more than a chemical-physical process. Every natural variety has an "erbstock"—surrounded by changeable genes—braving every change and not being susceptible to any decisive influence by crossing or external measures. By external influence we are not able to root out a series of unwelcome qualities, summarized under the designation "hereditary taint" at best we can shift their manifestation. We cannot overcome our inheritance, and we must take into consideration the recessive hereditary disposition of diabetes. This experience restricts our prophylactic dealing regarding diabetes.

Nevertheless the prophylactic-therapeutical work in this disease must become more intense. The premise for a successful effort would be to recognize more frequently and at an earlier stage a diabetic disposition. We ought to pay attention not only to the patient, but also to his relatives. Since by thorough questioning we are only able to recognize a small part of the latent cases, the physician ought to become acquainted with the simple methods by which an earlier diagnosis of the diabetic disposition is possible. The most simple method is the determination of the fasting blood sugar. More improved is the diagnosis of a latent diabetes by the dextrose tolerance test. Of course, other diseases exerting an influence upon the blood sugar curve must be excluded beforehand. The chance of a prophylactical-therapeutical success in diabetes candidates is great. Subjective and clinical manifestations of the disease can be prevented. Therefore the different exogene factors, environmental influences which cause the advance and slackening of the development of diabetes and obesity must be recognized. The old dietetic treatment, in former times the only treatment at our disposal, retains its full value in this respect. Early restriction in the administration of nourishment is necessary. We must be cautious against overfeeding with fat and exaggerated administration of carbohydrates, especially cakes and sweets. Every peasant knows that we are able to fatten animals by abundant amounts of carbohydrates. Vegetables and fruits should be preferred in the food. Obese persons with latent diabetes have to be calorically underfed, but they ought to get a sufficient amount of carbohydrates. Underfeeding too greatly intensified regarding the calorical values and a suggested withdrawal of protein must be avoided in regard to diabetes candidates. Joslin says: "Relatives of diabetes must be instructed never to allow their weight to go above the normal standard, and in fact after the middle of the fourth decade to keep the weight 5 to 10 per cent below such standards." Of importance is the right choice of profession. Sedentary occupations are to be avoided. Where there is

significant alterations from the normal. There is no royal road to an easy differential diagnosis of abdominal distress.

12. Case reports are given to illustrate some types of cardiovascular disease that give rise to pronounced gastro-intestinal symptoms.

Fundamental Facts of the Prophylaxis in Diabetes Mellitus

By

ERNST LYON, M.D.

JERUSALEM, PALESTINE

THE doctrine of diabetes is still full of doubts and contradictions and burdened with many a prejudice. We have seen in recent years a continuous wavering in regard to the fundamental pathogenetic and therapeutic views on diabetes, and in the future also we can expect surprises in this respect. The views on the prophylaxis of diabetes depend to a great extent upon the different theoretical views of the investigators.

Diabetes is a recessive disease, which originates from the hereditary disposition and it can be traced to a defective disposition of the insular apparatus of the pancreatic gland. On the other hand some well-known investigators favor the hypothesis that diabetes is often an acquired disease. The characteristic feature of diabetes is the lack of insulin; the most direct and important consequence of this lack of insulin is that the formation of glycogen in the cell—above all in the musculature, less in the liver—is being made difficult. The recessive hereditary disposition has been proved by investigations regarding family-pathology and twin-pathology. The discordant behaviour of enzygotic twins indicates the influence of environmental factors. The complete disharmony of behaviour of enzygotic twins has to be explained by unusual oscillations in manifestation (Störring). Heredity is the basis of diabetes, as Joslin says. He and his co-workers, White and Pincus, believe that it is highly probable that the development of diabetes depends primarily upon the transmission of the single recessive gene and the operation of one or more secondary factors. Pannhorst draws conclusions from the hormonal connections and from the variety of origin and severity; he thinks that among others not a single Mendelian gene, but probably "multiple allele" are decisive for the hereditary disposition of diabetes.

The question of the apparent or absolute increase of diabetes occupies a large space in modern literature. The graduated aging of the population, the reduction in the mortality from acute diseases, the improved early diagnosis of diabetes and better treatment, the consideration of social conditions led to an increased frequency and hence to an apparent relative increase in the number of diabetics. The absolute increase in diabetes is not due to a real increase of the hereditary disposition. The greater absolute frequency of diabetes is explained by an increased effect of exogene factors, which, in their turn, cause the disease. As causes are named the increased consumption of fat, the migration from agriculture into the towns, into professions with insufficient bodily exercise. Joslin thinks that "the increase is absolute as well as relative and that through a multitude of causes which lead to it, obesity brought about in a multitude of ways by our modern civilization is the chief inciting factor." "The hereditary tendency to diabetes is potential, a provocative force is required, before it becomes manifest."

He judges the influence of occupation also according to the opportunity of producing overweight. According to Lawrence "among the more immediate causes the most noticeable are over-eating and obesity." "The underweight is an insurance against diabetes."

It is well-known that some obese persons get sugar with the exactness of an experiment as soon as their weight exceeds a certain limit (Grafe). Juvenile obesity especially frequently develops into diabetes, and obese families are frequently diabetic families. It has been assumed that an exhaustment of the increte production could perhaps occur by exaggerated use of the increte production over many years by over-feeding (Thannhauser). Van Noorden and Isaac state, like many others, the frequent simultaneous occurrence of diabetes and obesity, refuse, however, to place obesity due to over-feeding in the forefront of diabetes etiology, so to say, to identify the exciting cause of exogene obesity and diabetes. According to Joslin, heredity seems to be the most important link in the chain of diabetes from generation to generation. But he speaks of obesity as having central importance. "In the adult obesity brings out the predisposition to the disease." "Obesity is preventable." Therefore it is within our power to avoid diabetes. The experiment of the Great War, during which diabetes was reduced by lack of nourishment in Germany, would favour this hypothesis.

Submitted March 3, 1937.

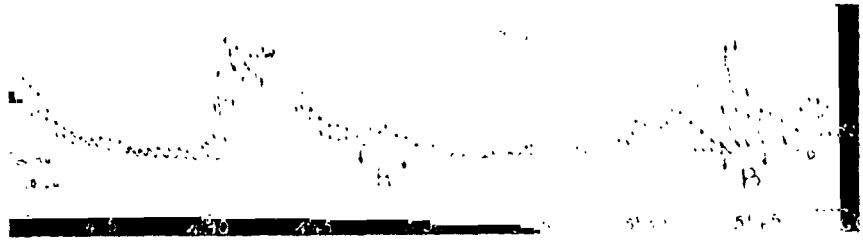

Fig. 1. Dog's colon, showing "B," increased muscular activity stimulated by the taking of food by mouth. (Feeding reflex) "A" shows the absence of the feeding effect when fed through a gastric fistula, showing that this reflex is not a gastrocolic reflex but a true appetite or taste reflex.

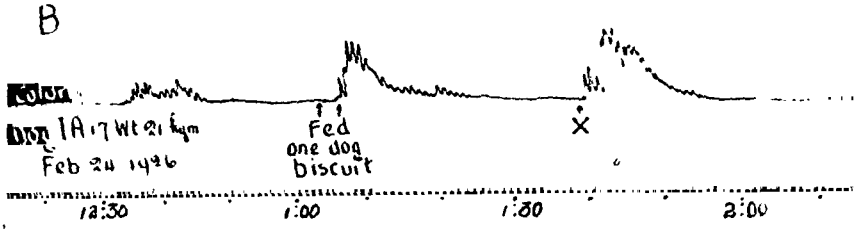

Fig. 2. Colon tracing dog, showing typical feeding reflex and a second psychic reflex at "X," initiated by the entrance of the dog's keeper who regularly fed the dogs.

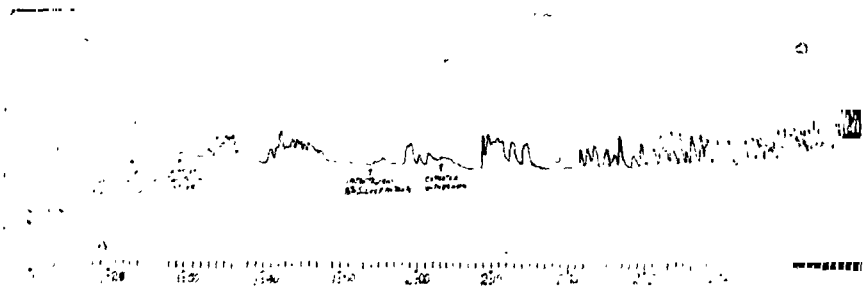

Fig. 3. Tracing of normal human colon showing increase in peristalsis and tone associated with trauma to the right ureter. Twisting of the catheter in the ureter caused painful contractions to occur in the colon on the left side of the abdomen. Injection of 6 c.c. of ½% silver nitrate caused further increase in muscular activity of the colon consisting of tone changes and painful contractions. These continued until they reached such severity as to require an opiate. The painful contractions in the colon occurred with pain in the right kidney tract and independent of the pain in the right kidney tract.

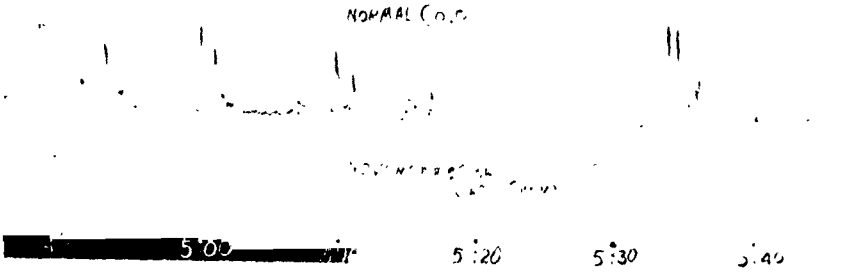

Fig. 4. Normal tracing human colon showing infrequent contractions and almost complete absence of tonal changes. Water pressure one inch.

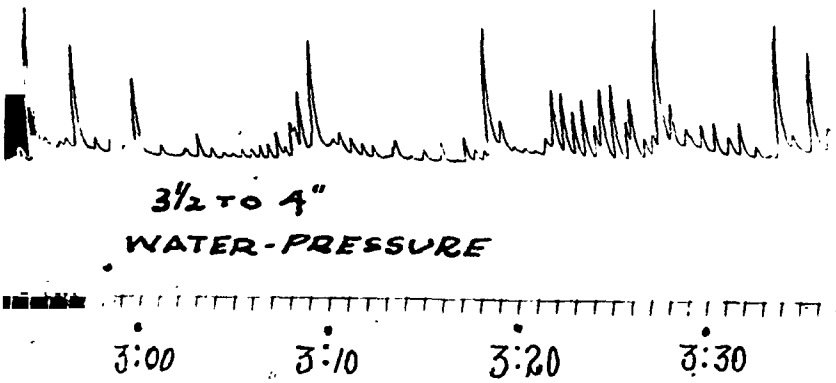

Fig. 5. Normal human colon tracing showing increased muscular activity produced by moderate distention of colon walls.

spasm of the colon. The correction of constipation by the removal of a diseased appendix or gall bladder has doubtless come within the experience of all of us. The association of rectal tenesmus with the strangury of cystitis or a diseased prostate has been a common experience. Distention of the normal sphincter ani regularly causes reflex increase in muscular activity of the colon higher up, particularly in the rectum. The ureters are frequent sources of reflex stimuli to the colon. In one instance during catheterization of the right ureter, the colon was stimulated to violent activity resulting in defecation during the cystoscopy.

The relationship between urologic disease and digestive symptoms has been investigated by the author and associates in urology. Studies were made of the effect of ureteral trauma upon the muscular activity of the colon. A volunteer woman with a permanent colostomy was used. A recording balloon was inserted into the proximal loop of colon through the colostomy; a kymographic tracing of the colon was made in the usual manner. After the colon had accommodated itself to the presence of the balloon, the patient was cystoscoped and a ureteral catheter was quickly passed to the pelvis of the right kidney. The catheter was then twisted to produce irritation in the ureter. Silver nitrate ½ of 1% was injected in the amount of 6 c.c. and the catheter was withdrawn.

During the insertion of the cystoscope and ureteral catheter, there was an apparent inhibition of colon peristalsis. Twisting of the catheter produced an aching pain in the region of the right kidney followed shortly by painful contractions of the colon on the left side at the site of the balloon. Injection of silver nitrate was followed by still further contractions in the previously resting colon. These contractions increased in amplitude and frequency. Each contraction of the colon was accompanied by left sided pain, with or without pain in the right kidney tracts (Fig. 3).

These painful contractions in the colon probably represent the mechanism of production of symptoms apparently arising in the colon associated with obstructive lesions in the ureters.

Apparently the ureter, rather than the kidney pelvis, is the chief source of this reflex irritation, as trauma of the kidney pelvis alone produced relatively slight reaction in the colon, whereas trauma of the ureter, produced by twisting the ureteral catheter and the injection of silver nitrate, caused marked changes in the muscular activity. These changes consisted of increased frequency and amplitude of peristaltic contractions and a very definite elevation in muscular tone.

INTRINSIC FACTORS INFLUENCING THE MUSCULAR ACTIVITY OF THE COLON

While studying the effect of feeding on the muscular activity of the colon, marked variations were found to occur. These variations were influenced largely by the character and amount of residue occupying the lumen of the colon. When the colon was completely empty and a small recording balloon was inserted within its lumen, the muscular tone of the colon was uniformly low and periods of peristaltic activity were few and usually of low amplitude and short duration due to the absence of distention or irritation.

When the colon was full of fecal material and a balloon was introduced, or when a very large balloon alone was used, the muscular activity was excessive with marked and very irregular tone changes with superimposed, usually exaggerated, peristaltic waves with very short periods of relaxation.

A recent study of the effect of distention upon the muscular activity of the colon has been made by the author in humans who had permanent colostomies. In this series of experiments, five negro women so operated upon were observed.

Condom balloons were inserted into the colon, both proximal and distal to the colostomy openings. The balloons were distended with water with varying levels of hydrostatic pressure controlled by a separatory funnel. The changes in muscular activity were recorded on the kymograph with the recording device which the author has perfected.

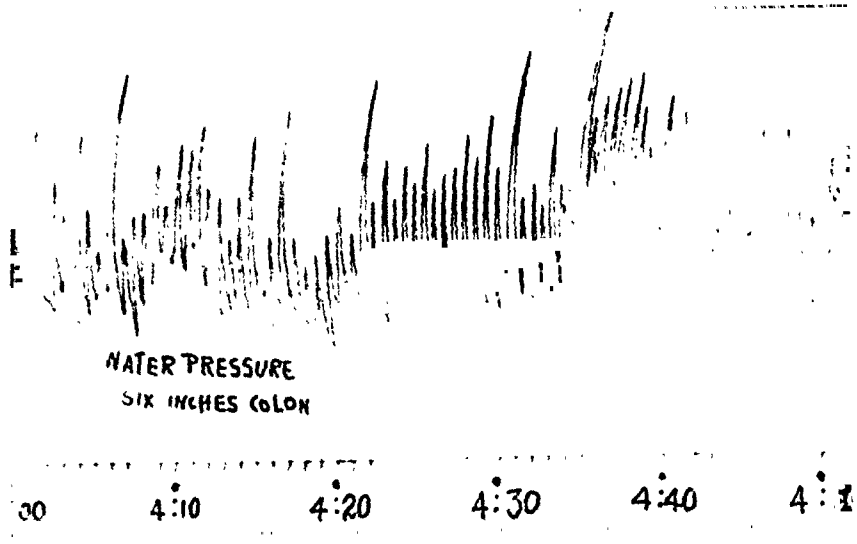

Fig. 6. Tracing normal colon, showing marked increase in muscular activity of the colon consisting of rapidly recurring deep peristaltic waves with definite tone changes.

With a water pressure of one inch or less, the colon was quiescent most of the time with occasional contractions without much tone change. These contractions occurred irregularly and were usually of short duration (Fig. 4).

Increase of the water pressure in the thin walled elastic condom balloon invariably increased the frequency of contractions and the tone changes. The increase in the muscular activity of the colon was proportional to the increase in water pressure and distention of the bowel wall.

The changes in the muscular activity of the colon varied with the degree of distention from a moderate increase in frequency and amplitude of contractions to a continuous activity with constant, rapid and extensive contractions with well marked tonal changes as shown in Figs. 5 and 6.

The degree of increase in muscular activity varied in different colons and also in the same colon at different times but was always similar in character. These tracings were made in quiet surroundings, the subject lying comfortably and relaxed, usually sleeping while the prolonged tracings were being made.

EFFECT OF PROLONGED DISTENTION UPON THE MUSCULAR ACTIVITY OF THE COLON

With prolonged distention, the irritability of the colon gradually lessened, the tonus slowly lowered, the intervals of contractions were of shorter duration and less extensive until usually within one to two hours the tracing resembled a resting colon with normal pressure (Fig. 7).

Lowering of the pressure within the colon lumen for several minutes followed by an increase in pressure usually resulted in several small contractions followed by prolonged rest.

This loss of irritability of the colon musculature after prolonged distention is probably similar to that observed in the rectum, when the call to defecation having been repeatedly ignored the defecation reflex becomes depressed or sometimes almost completly obliterated. It is possible that this loss of irritability

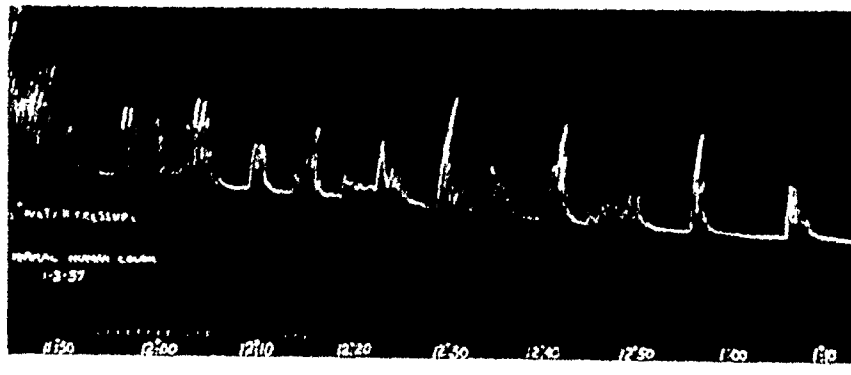

Fig. 7. Tracing of the normal human colon showing the effect of prolonged distention upon the muscular activity, consisting of wider intervals between peristaltic contractions and a gradual slow loss of tone, wider resting intervals between periods of contraction.

may be responsible for stasis in the proximal colon and cecum. Certainly the colon is not in spasm after prolonged distention and it may be that our conception of colon stasis as almost always being "spastic" in origin is a miscomprehension. It is not likely that the smooth muscle of the colon has become fatigued in this short period, for distention for a period of less than two hours usually sufficed to produce inhibition of peristalsis and tonus. It is more likely that this apparent inhibition is due to loss of irritability of the neuromuscular apparatus. Studies of the reaction of the denervated gut have not been made by the author.

The increased activity of the colon musculature with distention is certainly intrinsic and represents in part, at least, the characteristic response of isolated smooth muscle to mild stretching. Bayliss and Starling (7) in 1901 stated that "peristalsis in the denervated gut was started by the stimulation of local nerve plexuses by the presence of a stimulating agent within its lumen."

Irritating substances introduced into the colon likewise cause marked changes in activity. Plant and Miller (8) found that "introduction of cinnamon water (U.S.P.) caused a distinct rise in the tone accompanied by an increase in amplitude of the large contraction waves." The introduction of even isotonic solutions of magnesium sulphate into the dog's colon produced a marked increase in muscular activity, possibly by distention.

It is improbable that normal fecal residues ever distend or irritate the normal colon as was done in these experiments but it is possible that the stuffing of patients with irritable colons, with high residue and roughage diets does produce an aggravation of the already existing irritability both by distention and local irritation similar to that produced experimentally.

Prolonged retention of large fecal residues probably eventually raises the threshold of irritability of the colon and may produce stasis not only at the rectum but in any part of the colon where such prolonged accumulations occur by loss of excitability of the neuromuscular apparatus.

These observations indicate that the amount and character of residues within the lumen of the colon are potent factors in determining the character of its muscular activity and must be recognized and appreciated as fundamental factors in any course of management intended to correct colon disorders.

SUMMARY

It has been shown that the muscular activity of the normal colon is influenced by many factors, both extrinsic and intrinsic.

It has been shown that feeding by mouth produces a reflex activity in the colon and that feedings through a gastric fistula produce no reflex and that this is an appetite or taste reflex and not a gastrocolic reflex.

The effect of psychic stimuli upon the colon musculature has been discussed.

It has been shown that stimuli arising in adjacent viscera have a profound influence upon the muscular activity of the normal colon.

The effect of distention upon the colon musculature has been shown; also the effect of prolonged distention has been shown and discussed.

Human Autonomic Pharmacology

8. The Effect of Iontophoresis on the Gastric Juices with especial reference to Acetyl-Beta-Methyl Choline Chloride (Mecholyl)*

By

JULIUS LOMAN, M.D., MAX RINKEL, M.D.

and

ABRAHAM MYERSON, M.D.

MATTAPAN, MASSACHUSETTS

THE use of the galvanic current for the introduction of drugs through the skin began with the investigations of Frankenhäuser (1) in 1898. His studies were followed a few years later by those of LeDuc (2). This method of therapy became known as iontophoresis. Since this early work, numerous publications on the theoretical and clinical aspects of iontophoresis have been written. Especially has the method been used in the field of ophthalmology, where it was introduced in 1908 by Wirtz (3). Many other workers, including Schnyder (4), Bos (5), and Erlanger (6), have utilized iontophoresis with various drugs in diseases of the eye.

One of the most recent drugs introduced into the body by the technique of iontophoresis is acetyl-beta-methylcholine chloride or mecholyl, particularly in the treatment of arthritis, peripheral vascular disease, myositis and skin ulcers, Kovacs (7), Abel (8), Saylor, Kovacs and Duryee (9). Kotkis and Melchionna (10) observed the effects of mecholyl iontophoresis on dogs. They concluded that the positively charged part of the mecholyl molecule is liberated at the positive pole of the galvanic current into the capillaries of the skin where it is probably taken up by the blood. Their control experiments, in which physiological salt solu-

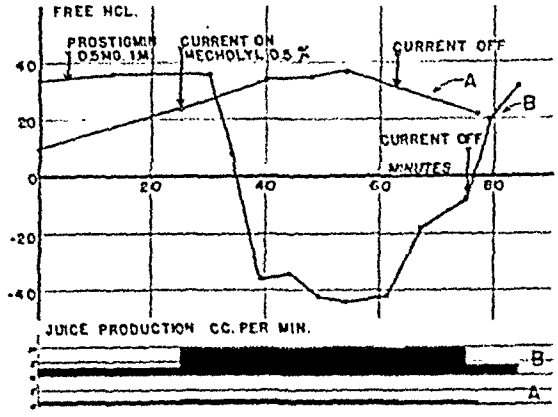

Chart 1. The effect of iontophoresis on the gastric juice with (a) mecholyl alone, and (b) with prostigmin and mecholyl. In this subject mecholyl alone was not effective in diminishing the acidity of the gastric juice, but when it was combined with prostigmin the juice became rapidly alkaline and increased in amount. These changes continued for approximately forty minutes, when the current was turned off.

tion was used in place of the mecholyl, gave negative results.

Kovacs (7) observed that a 1% mecholyl solution applied over arthritic joints causes the following local and general changes: local sweating for a period of eight to ten hours, increased temperature of the skin, an increase in capillary flow without enlargement of the capillaries, slight redness of the skin, a questionable slight increase in the leukocytic count, a feeling of warmth, a reduction of the swelling, increased mobility and relief from pain. Flushing, generalized sweating, increase in pulse rate, salivation, slight lowering of blood pressure, and evidence of intestinal peristalsis occurred. That the drug penetrates the skin through the positive galvanic pole has been definitely demonstrated by Alexander and Kotkis (11), who found that a substance identical in its physiological action with mecholyl was present in the perfusate in the hind limbs of animals following iontophoresis.

The introduction of mecholyl into the body by iontophoresis may be compared to a widespread intradermal injection of the drug (12). By either method two effects are obtained: (1) a local sweat reaction, and (2) if the dose is sufficient, general effects of the drug are obtained. Thus, we have demonstrated that if an electrode the size of a quarter is used as the positive pole, a local sweat reaction at the zone stimulated and practically identical with that resulting from a local intradermal injection with mecholyl is obtained. If several intradermal injections of very dilute solutions are made on a subject, not only does a local sweat reaction develop, but general sweating and all the other effects produced by a moderate to a large subcutaneous injection of the drug appear.

In a previous communication Myerson, Rinkel and Dameshek (13) definitely demonstrated that mecholyl alters the character of the human gastric secretion so that the quantity increases, the acidity diminishes, pepsinogen disappears, and mucus appears in large quantities. These changes in gastric function were observed to be as rapid in their occurrence as were the other manifestations caused by the injections of mecholyl in doses between 20 and 30 mg. and wore off in about the same length of time. Furthermore, it was shown that the changes in gastric secretion could be completely prevented or abolished by atropin and enhanced by the administration of physostigmin or prostigmin. For example, 1/50 to 1/100 gr. of atropin given simultaneously with or prior to the injection of mecholyl regularly checked the production of an alkaline mucus juice as promptly as it did the other effects of the drug. Again, when given at the height of the mecholyl reaction, atropin caused a rapid return of the juice to its original character. On the other hand, doses of mecholyl too small to be very effective in changing the reaction of the gastric juice, when combined with prostigmin or physostigmin, created as marked changes in the gastric secretion as did moderate to large doses of mecholyl alone. The synergism of prostigmin and mecholyl is as regular as the antagonism of mecholyl and atropin not only on the gastric function but also on the other autonomic functions of the body which we have studied. It should be emphasized here that although it is usually safe to give mecholyl in dosage of 25 mg., it is definitely hazardous to give more than 10 mg. of the drug when combined with prostigmin.

Because mecholyl when given by the parenteral route is explosive and quite transient in its effects, the method of iontophoresis was utilized in the present study in an attempt to produce slower and more prolonged changes in the gastric juice. In addition, the present study includes the use of benzedrine, histamin, and prostigmin introduced into the body by iontophoresis.

MATERIAL AND TECHNIQUE

The same group of subjects who were given mecholyl by subcutaneous route in the study by Myerson, Rinkel and Dameshek (13) were utilized. The experiments were carried out under similar basal conditions. Before the application of the electrodes, a stomach tube was passed and maximum amounts of gastric juice removed at short intervals. The juice was examined for free hydrochloric acid, combined and total acids and, in a few instances for its pH con-

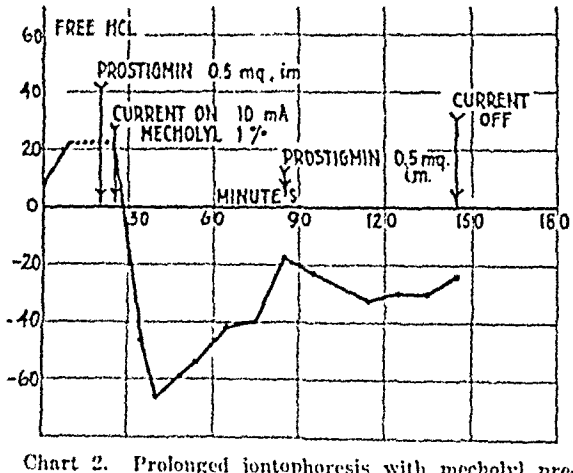

Chart 2. Prolonged iontophoresis with mecholyl preceded and followed by prostigmin. The gastric juice remained alkaline for approximately two hours, when the current was discontinued.

centration. Large rectangular electrodes, measuring 8.5 inches by 6.5 inches, the positive one placed over the abdomen and the negative one over the lower back, were used. The electrodes were wrapped in gauze and finally covered by rubber sheeting which encircled the abdomen. The positive electrode was kept saturated with either mecholyl, usually a 1% solution; benzedrine, a 1% solution; histamin, a 1:10,000 solution; and prostigmin, a 1:2000 solution. The negative electrode was saturated with normal salt solution. After all the juice obtainable was removed, the current was applied, usually in the strength of 15 milliamperes and at short intervals maximum amounts of gastric juice were recovered. In most instances in which mecholyl was used, the subjects previously received prostigmin (0.5 mg.) or physostigmin (gr. 1/100) by subcutaneous route. When prolonged administration of mecholyl by iontophoresis was carried out, the gauze covering the positive electrode was removed at one hour intervals and saturated with fresh mecholyl solution. The blood pressure, pulse, and the visible effects of the drugs were noted throughout the experiment.

RESULTS

1. Control observations. In order to determine whether the changes noted in the gastric juice were due to the penetration of the drug itself and not to other factors involved in the experiment, the following observations were made:

(a) The effect on the stomach juices of galvanization with either water or salt: In several instances it was observed that no specific changes occurred in the acid level or quantity of the gastric juice.

(b) The factor of heat created by the galvanic current applied to the skin: In several subjects the gastric juice was examined following the application of a hot water pad over the abdomen. Under such conditions no definite changes were noted in the character of the gastric juice.

2. Iontophoresis with mecholyl.

(a) The administration of mecholyl by iontophoresis was carried out in the following manner on three subjects:

In the case of the first subject, who was given 1% solution of mecholyl by this method, a fall in the free HCl of the stomach juice from 12 to an acid deficit of 14 resulted. Associated with this change there was a slight generalized perspiration. Later, the same subject was given 1.3 mg. of atropin subcutaneously prior to the mecholyl iontophoresis. No significant change in the gastric acidity now resulted.

In another subject, iontophoresis with a 5% solution of mecholyl and with a current of 30 milliamperes resulted in a change of the gastric pH from 1.91 to 8.33, associated with moderate generalized perspiration.

In the third subject, no change in the gastric secretion occurred, when a 0.5% mecholyl solution was used, but later a definite drop in the acidity to the alkaline side (from 34 to -42) occurred when the mecholyl iontophoresis was preceded by the administration of prostigmin (0.5 mg.) (Chart 1). Accompanying this change there was moderate generalized sweating.

(b) In ten other subjects the mecholyl iontophoresis (1%) was preceded by a subcutaneous injection of prostigmin (0.5 mg.). In every case there resulted a rapid disappearance of free HCl from the stomach and an increase in the mucus content, these changes lasting from forty minutes to longer than one hour (Table I).

The quantity of mucus produced by the stomach was comparable to that observed when the drug was given by subcutaneous route. Most of the ten subjects exhibited moderate to marked perspiration. Samples of gastric juice taken at various intervals following the administration of the prostigmin showed no change towards the alkaline side. The sudden changes in alkalinity and the increase in mucus occurred soon after the administration of mecholyl, usually within ten minutes. The pulse rate was observed to increase in all but two of the cases in which it was followed, the increase varying from 12 to 42 beats per minute. One case showed a secondary slowing of pulse. In four cases a drop of blood pressure ranging from 16 to 30 mm. occurred.

(c) In two subjects the period of iontophoresis was extended for approximately two hours (Chart 2). It was found that the alkalinity of the gastric juice could readily be maintained and controlled by: (1) repetition of the dose of the prostigmin an hour after the first injection; (2) renewal of the mecholyl solution; and (3) adjustment of the strength of the

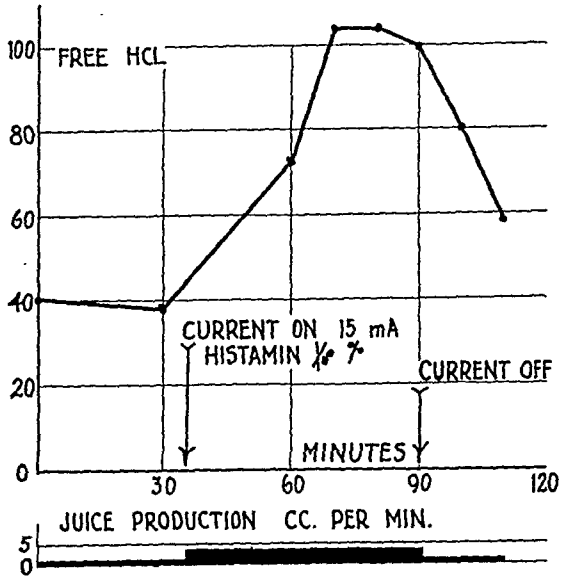

Chart 4. Iontophoresis with histamin: Note the marked increase in gastric acidity associated with the increased production of gastric juice.

galvanic current. Since the juice becomes alkaline with the appearance of the general effects of the mecholyl, the current was adjusted to the lowest milliamperage necessary to produce slight sweating of the face. Thus, a milliamperage between 5 and 10 was found to be sufficient to keep the gastric juice at an alkaline level. By this technique, the discomfort to the patient was minimal over a period of two hours or longer.

3. Iontophoresis with benzedrine. Benzedrine was administered by iontophoresis to four subjects. The experiments were followed for approximately two hours. Only two subjects showed a significant increase in gastric free HCl. There was, however, a rise in blood pressure in every case ranging from 9 to 34 mm. of mercury, which indicated that the benzedrine had been absorbed (Chart 3).

4. Iontophoresis with histamin. For comparison with benzedrine, two subjects were given histamin (1:10,000) by iontophoresis. In the first case, the free HCl rose from 7.5 to 114. No change in pulse or blood pressure was noted. In the other subject, there was a change in the free HCl from 38 to 104, associated with a fall in blood pressure of 20 mm. of mercury, but with no change in pulse rate (Chart 4).

5. Iontophoresis with prostigmin. Prostigmin (1:2000) by iontophoresis was administered for approximately one hour to two subjects. No specific effect in the gastric juice was noted in either case, the HCl showing normal variations throughout (Chart 5).

COMMENT

The foregoing results indicate definitely that the changes produced in the gastric juice by mecholyl iontophoresis, particularly when preceded by the administration of prostigmin are comparable with the changes produced by a subcutaneous injection of the drug, namely, the production of an alkaline mucous juice usually within ten minutes following the beginning of iontophoresis which is associated with the general effects of sweating, increase in pulse rate, and fall in blood pressure. The administration of the drug by iontophoresis, however, is capable of more prolonged and not so explosive effects as it is by the subcutaneous route, since the drug is more slowly absorbed and better controlled by the former method. It is, therefore, not so apt to cause sudden drops in blood pressure as by subcutaneous administration. For these reasons the method of iontophoresis is the one of choice for the administration of the drug in its possible therapeutic use for gastric ulcer in which an alkaline gastric juice is desirable. Prolongation of the alkaline mucous gastric juice for periods of two or more hours can be effected by repeated subcutaneous doses of prostigmin followed by replenishment of mecholyl solution on the positive electrode and adjustment of the strength of the current. By these means a slight generalized reaction can be maintained with the minimum discomfort to the patient. Since the point at which the gastric juice becomes alkaline corresponds with the onset of the general effects of the drug, perspiration may be taken as an index of the reaction of the juice. Thus, if mecholyl iontophoresis is used as a method of therapy in gastric ulcer, intubation would be rendered unnecessary. The administration of prostigmin prior to the mecholyl iontophoresis is highly recommended since with mecholyl alone production of a mucous juice may not be sufficiently marked or regularly obtained in some instahces (14). It is clear that the effects described above are definitely due to the penetration of mecholyl into the body, the other factors of the method playing little or no important role.

The results obtained by iontophoresis with benzedrine are not so striking as those obtained by mecholyl. The observations made on the four subjects studied indicate that there is a slight increase in the acid level of the gastric juice, but this is not so clearly evident as when the drug is administered by subcutaneous injection (15). That the benzedrine enters the body by iontophoresis is, however, indicated by the fact that there is a definite rise in blood pressure

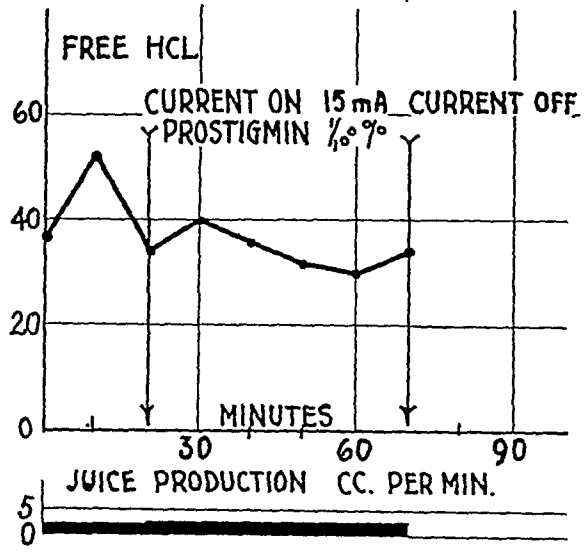

Chart 5. Iontophoresis with prostigmin: There is an insignificant effect on the level of acidity and production of the gastric juice.

associated with the slight increase in gastric acidity. It is obvious that the drug, when given by iontophoresis, does not penetrate the body in sufficient quantity to create as great changes as it does following a subcutaneous injection (13).

The alterations in the gastric juice following histamin iontophoresis are as striking as those obtained by mecholyl iontophoresis. The histamin molecule obviously very effectively penetrates the body, creating as marked an increase in the gastric acidity as is obtained following the subcutaneous administration of the drug.

Although prostigmin given by subcutaneous route is capable of producing an alkaline gastric juice, it does so very slowly and in much longer time than does mecholyl itself. These observations have been made by Myerson, Rinkel and Dameshek (13) in the previously mentioned study. By iontophoresis, prostigmin does not appear to penetrate the body, at least in sufficient quantity to cause any definite change in the gastric juice.

CONCLUSIONS

1. The administration of mecholyl by iontophoresis produces an alkaline mucous gastric juice as effectively as it does when given by subcutaneous injection. Furthermore, the method of iontophoresis with mecholyl for the production of an alkaline juice has distinct advantages over its administration by subcutaneous route, namely, the effects of the drug are not so explosive; the drop in blood pressure is not so sudden or marked; and the period of time of the alkalinity is markedly increased. For these reasons the former method would appear to be the method of choice for its possible therapeutic application in gastric ulcer. The administration of prostigmin before iontophoresis of mecholyl is strongly recommended, since the effects of mecholyl are regularly enhanced. By the use of these two drugs the alkalinity of the gastric juice can be maintained for two hours or longer.

2. Iontophoresis of benzedrine causes a slight increase in the acidity of the gastric juice associated with a rise in blood pressure. These changes are not so marked as when the drug is administered by parenteral route.

3. The administration of histamin by iontophoresis results in a much greater increase in gastric acidity than does benzedrine.

4. The administration of prostigmin by iontophoresis causes no significant changes in the acid level of the gastric juice.

Electro-Coagulation of Rectal Cancer*

By

R. PITANGA SANTOS, M.D.†

IN the treatment of rectal cancer we can from the outset exclude radium and X-rays. Radium is difficult to use in the requisite amount. Even when well placed with the help of the proctoscope, it is not easily kept *in loco* for the necessary length of time, on account of contractions of the rectum. Furthermore, the mucous membrane of this organ is very sensitive to radium. This sensitiveness can be noted even when radium is applied to adjacent regions. I have known cases in which the use of radium on the cervix of the uterus has produced intense rectitis with early stricture, and sometimes deep necrosis, with eschar formation on the rectal wall. In the last three years I have found three cases of this kind. The difficulty of keeping radium tubes in place (on the affected area) makes its use in the rectum dangerous.

X-rays cannot reach the tumor in sufficient dosage, on account of the deep location of the rectum and of the bony pelvis that surrounds it. The disadvantage of direct application through a tube inserted into the rectum, such as the Schaefer-Witte apparatus, is that the patient cannot endure it because the application

*Reprinted from *Revista Brasileira de Cirurgia*, No. 2, Feb., 1936, translated by Prof. Carlos E. Kany, University of California, Berkley, California.

†Member of the University of Rio de Janeiro Medical Faculty and of the Brazilian College of Surgeons.

Submitted April 30, 1937.

takes a long time. It would be possible only with a million-volt apparatus, permitting a short treatment of 3 or 4 minutes. However, such an apparatus is very expensive and the treatment would be economically of great cost.

There remain surgery and electrocoagulation. Other treatments have been employed; we are now attempting pasteurization of the tumor by means of short waves. The results are still too uncertain and recent to be reported.

There is also the compressed-oxygen treatment, which Prof. Osorio de Almeida has been using with satisfactory results (according to the author). This treatment, unfortunately, necessitates high-voltage X-rays. It is slow and costly, and in many cases cannot be employed. Moreover, results for rectal cancer have not proved satisfactory, at least until a short time ago. Recently the author has used radium together with oxygen, and has seemingly had better success. In any case, it is not a practical method because it is drawn-out and expensive.

As for surgery in rectal cancer—the earlier the operation the better the results. Unfortunately, this is not always possible. Early diagnosis is generally a matter of chance, because rectal cancer develops quietly during the first few months. Its only usual symptom does not alarm the patient: stubborn constipation. It causes neither pain nor pressure nor bleeding. If, by chance, a doctor is consulted, he likewise suspects nothing, in view of the absence of other symptoms. Therefore, the surgeon has an opportunity to operate only on very advanced cases. Nevertheless, surgery in rectal cancer is, in the majority of cases, successful. Therefore I am not trying to combat surgery, for I have resorted to it myself on several occasions. Still, it has fewer advantages than has coagulation. It is a more serious operation, more hemorrhagic and more subject to recurrence of the malady.

With electrocoagulation the operation can be performed without loss of blood and without shock to the patient. Even under the poorest conditions of operability, the patient emerges looking none the worse. Furthermore, it is an economical operation. When conditions are identical, given an incipient cancer in the rectal ampulla, surgery removes the whole rectum, from the anal to the sirmoid, whereas electrocoagulation destroys only the tumor and preserves the rest of the rectal ampulla.

Often this operation can be performed at one time, and only in very advanced cases is it necessary to fashion an iliac anus. My experience in coagulation leads me to prefer it to surgery. I have made 35 coagulations on very advanced tumors without a single death from operation. Of these 35 coagulated cases, 8 died of metastasis; 27 are living:

1 has been cured 7 years.
4 have been cured 6 years and 8 months.
3 have been cured 6 years and 2 months.
1 has been cured 6 years and 3 months.
1 has been cured 4 years and 9 months.
3 have been cured 3 years and 6 months.
2 have been cured 2 years and 9 months.
2 have been cured 2 years and 6 months.
5 have been cured about 5 years.
5 were coagulated this year

The technique and instruments of diathermo-coagulation are well known. I use an apparatus of 6 amp. because our service does not permit the use of a stronger one. There are apparatuses of 20 amp., like that of Kayser in Berlin. With a 6 amp., coagulation is slower and more laborious, but good results can be obtained. The tumor is coagulated progressively from the surface downward. As the tissues become coagulated, they must be curetted, because if a thick layer of coagulated tissue is allowed to remain, the deeper tissues will not be destroyed. The electrocoagulator must be constantly cleaned, because coagulated tissue adhers to it. The technique is slightly blind. One works with a diathermo-coagulator as with a curet in osteomyelitis. Cancerous tissue is coagulated more easily than healthy tissue; in that way one knows when one has reached normal tissue. The only safe rule is to proceed cautiously, attentively and slowly. The only guide is the hardness of the tumor, which contrasts with the adjoining tissues. A digital examination must therefore be made from time to time. In the lower half of the ampulla, nothing need be feared. In the upper half, however, one runs the risk of perforating the bladder or the peritoneum. Yet this will occur only when the tumor extends to those regions. That has never happened in the coagulations I have performed.

When the tumor has been destroyed, the last layer of coagulated tissue should not be scraped. So that when the scar sloughs off, the surrounding tissues are protected by a defense layer and the peritoneal cavity will not be perforated. At least, that has always been so in my cases.

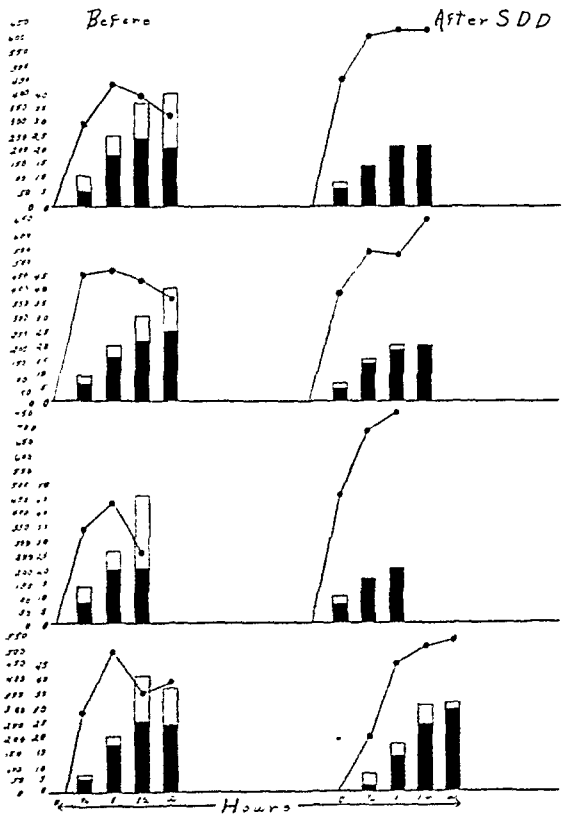
There remains the problem of perirectal adenopathy. As a rule I disregard it. In the great majority of cases, such adenopathy is only inflammatory. This fact has been proved by numerous authors and my experience agrees fully with theirs. Furthermore, cancer develops slowly in depth. It develops circumferentially, spreading over the mucous membrane of the rectum.

Lenthal Cheatle, surgeon in King's College Hospital, London, published in the February, 1914, issue of the *British Medical Journal*, an article with numerous microphotographs, showing longitudinal and transverse cuts of a rectal cancer, in which it is evident that cancerous cells are nonexistant adjoining the tumor. Penetration through lymphatic channels is also very slow, because we see large rectal tumors operated upon without emptying these ganglia and with a survival of 5 to 6 years and no local metastasis. Furthermore, any pericancerous adenopathy revealed by digital probe may likewise be coagulated.

This is the rule I follow: in incipient cases in which the tumor occupies a small part of the rectal circumference, I coagulate transanally after dilating the sphincter. In more advanced cases, I section the anal canal, in the posterior angle, as far as the coccyx, and I coagulate in the open, as it were. If the tumor occupies only half the circumference, I coagulate only that half, preserving the rest of the rectal ampulla. Healing takes place normally in 30 to 40 days, obtaining also a perfect healing of the anal wound, with the sphincter preserved. If the cancer occupies all the rectal circumference, coagulation must destroy the whole organ. Then a preliminary iliac anus is made which will facilitate the healing of the wound. In these cases, a fibrous tube remains in place of the

rectum. Sometimes this tube is sufficiently elastic to permit closing of the iliac anus. I have three such cases and for six years these patients have been doing well. When that does not occur, the patient keeps the iliac anus permanently.

Surgery could in such cases accomplish a lowering of the sigmoid and thus afford greater convenience to the patient. It is necessary to consider, however, that in these advanced cases the general health of the patient is precarious and such an operation is much more serious than coagulation. For advanced cases, diathermocoagulation, therefore, has the advantage of less risk to operative mortality.



In incipient cases it has the advantage of economy. One can destroy the tumor and keep the rest of the rectal ampulla, performing the operation without perforating ducts or lymphatics, because the tissues are progressively coagulated and curetted. And coagulation is best employed in beginning cases, because in these it is possible to destroy the tumor and preserve the rectum with a relatively small operation.

From this point of view coagulation has all the advantages of the nonsurgical methods (effecting the cure with no risk to the patient), and has the advantage of being easier, more rapid, and more economical.

THE DESIRABILITY OF MEASURING THE ACIDITY OF THE GASTRIC SECRETIONS RATHER THAN THAT OF THE GASTRIC CONTENTS

FOLLOWING the administration of a test meal the samples removed from the stomach contain the secretions which entered the stomach mixed with and diluted by a variable and unknown quantity of the fluid given with this test meal; this mixture constitutes the *gastric contents*. It is often, and in fact, usually assumed that the acidity of the *gastric contents* bears a direct and constant relationship to the acidity of the *gastric secretions*. Under many conditions this is not true and the failure to recognize the difference which often exists has led to a great deal of confusion in studies on gastric acidity.

When secretogogues are placed in the stomach, secretion of acid begins rather promptly and may then continue for some time at a fairly high and constant rate, independent of the amount of the meal remaining in the stomach. Thus, in dogs with whole-stomach pouches, secretion may continue for considerable periods of time after the meal has been removed. Variations in the rate of emptying of the stomach may, therefore, cause marked changes in the acidity of the *gastric contents*, due to changes in the proportion between the amounts of test meal and secretions present. Such changes, naturally, need not be related to the changes which are taking place in the acidity of the *secretions* entering the stomach.

The following examples illustrate this point: I. Suppose that two patients are given the same type of test meal which contains 400 c.c. of fluid. Suppose that during the same test period identical amounts of secretion of exactly the same degree of acidity entered the stomach. If the rate of emptying was the same in both patients, then the acidity of the *gastric contents* would be the same in both. Suppose, however, that the rapidity with which the test meal leaves the stomach differs in the two patients, so that the *gastric content* removed from patient (A) consists of the secretions which entered the stomach plus 100 c.c. of the fluid given with the test meal, while in patient (B) only 50 c.c. of fluid given with the test meal is mixed with the secretions. Titration of the *gastric contents* would lead to the erroneous conclusion that patient (A) either secreted only one-half as much acid or that the acidity of his secretion was only one-half as great as patient (B) while in reality the amount and acidity of the secretions were identical and the only difference was that in patient (A) the secretions were diluted by twice the amount of fluid from the test meal. II. Following various surgical procedures the rate of emptying of the stomach is often markedly altered, and due to this fact titration of the *gastric contents* often fails to reveal the true changes produced in the acidity of the secretions entering the stomach. For example, if following a certain surgical procedure the acidity of the *secretions* were to be re-

duced to one-half its original value while at the same time the rate of emptying of the stomach was increased so that only one-half as much fluid from the test meal remained in the stomach to dilute the secretions, then the resultant acidity of the *gastric contents* would be the same as before the operation.

A similar type of reasoning will show that the acidity of the gastric *secretions* might be markedly increased by some procedure but if a corresponding slowing of the rate of emptying should occur, then the acidity of the *contents* would remain unaltered. These examples are not hypothetical but have actually been encountered in experimental work.

The above examples show that the acidity of the *gastric contents* cannot be used to study changes in the acidity of the *gastric secretions*; the two are distinct entities and should be measured separately. When histamine is given and the secretions removed from the empty stomach by continuous suction, it is the acidity of the secretions that is being studied. However, the results obtained in this way are of doubtful significance first, because histamine is the most powerful stimulus known for the secretion of acid and also probably an abnormal one, and under its influence many regulatory phenomena are prevented from exerting their effect; second, in this type of test the normal filling and emptying reflexes are absent and it is well known that they play an important role in regulating the acidity of the gastric secretions.

A better way of studying the acidity of the gastric secretions is to put some substance which is not destroyed or absorbed from the stomach in the fluid of the test meal and to determine the concentration of this substance in the gastric samples. When this is known, it is possible to say just how much of the fluid in the sample of gastric contents is fluid originally given with the test meal and how much is fluid of the secretions which entered the stomach. By dividing the acidity of the contents by the amount of fluid secretions which they contain, the true acidity of the gastric secretions can be obtained.

GASTRO-ENTEROLOGY AND THE OBESITY PROBLEM

GASTRO-ENTEROLOGY, including the science of nutrition, is the logical specialty to direct medical thought in the problem of obesity and to provide leadership for its proper control. Excessive weight with its associated diseases presents one of the greatest opportunities in the field of personal preventive medicine. Insurance statistics long ago established and have repeatedly re-established increasing mortality rates corresponding quite accurately to increasing degrees of obesity. Two-thirds of all people over forty years of age with fifteen pounds or more overweight show some degree of hypertension. This is controlled to an unappreciated degree by weight reduction. It is extraordinary that these statistics have been so largely ignored by the medical profession. The relationship of excessive weight to such conditions as diabetes, biliary tract disease, certain forms of hypertension, nervous and degenerative disease is undoubted. The numbers of cases in these groups run into the millions and apparently are increasing.

There are innumerable instances of successful and permanent weight reduction in marked obesity under intelligent medical supervision with extraordinary relief from distressing symptoms. It requires only a proper conviction and a little personal force on the part of the physician. With definite instructions and a balanced diet of milk, eggs, whole grain cereal, lean meat, green vegetables, and fruit, of proper total caloric value, it is thoroughly practical in a majority of individuals who seek medical advice, especially a periodic health examination, to attain and maintain a proper weight level. Impersonal propaganda is less effective and often unwisely applied. It is necessary to individualize, to follow the blood pressure in some cases and to see that the reducing program is carried out at a rate and under conditions that permit of proper readjustment of the digestive and circulatory organs. Then, as a rule, the patient has an improved sense of well being during the whole period of reduction.

There are obviously psychological reasons why the matter of obesity is so generally neglected. Some doctors do not like to give unwelcome advice or do what they think will be unpopular with the patient. It is only the superior physician who will persistently pursue the cause of vague symptoms into the field of pathological physiology after he is assured by elaborate tests that there is no organic disease. In the first place, preventive efforts never have the dramatic appeal of specific curative medicine and hence do not compete well for the busy doctor's time and interest unless the humanitarian spirit of service has been developed along with the scientific viewpoint. Moreover the patient may have had a prolonged period of malnutrition or a disease in which full nutrition is desirable. Even the physician in his desire to make the ulcer patient gain weight may forget that a great excess of weight predisposes to the recurrence of ulcer as well as to other troubles.

Indifference on the part of the profession toward obesity and indefiniteness in the matter of dietetic instructions are, however, reprehensible in other respects. Patients turn to dietetic fads, drastic reducing methods, incomplete diets, large amounts of thyroid extract, and even toxic drugs such as dinitrophenol after passing through the hands of regular physicians. Some irregular practitioners by unscientific methods and quite incomplete diets have even temporarily relieved obese patients. Nutritional deficiencies are very prevalent as has been emphasized by Minot and his associates. These deficiencies may exist with obesity and likewise call for scientific dietetic advice from the physician.

Newburg and others have shown by accurate measurement of the energy output and caloric intake that all obese individuals have invariably become fat simply and solely because they have eaten too much for their type and that they will all lose weight with sufficiently reduced caloric intake. The weight can even be predicted quite accurately under fully controlled experimental conditions. Glandular factors, of course, affect basal metabolic rates but are of minor importance in the practical management of obesity. Appetite is no safe guide to nutritional needs. Carlson has shown that the craving for food is largely a matter of memory of pleasant tastes and pleasurable satisfaction. The appetite can really be re-educated and after a period of adjustment the craving for excessive food may be largely lost. It is the problem of overcoming a bad habit. Newburg reported a case of

a 560 pound man reduced over a period of two years to 194 pounds. This patient maintained his weight at 194 pounds in health and at work and stated that he did not crave more food. In many individuals middle age with its decreasing metabolism calls for an intelligent control of eating habits to avoid excessive weight.

Discussions of obesity often sound pedantic and platitudinous and are very apt to end in levity especially when ludicrous figures are exhibited. Consequently, the fact that obesity plays an important part in health and even life is forgotten. It is anyone's privilege, if he chooses, to have the philosophy of "eat, drink and be merry" regardless of obesity but there is no use in deceiving himself as to the facts. He cannot successfully rationalize his follies on the basis of the facts. It is advisable in practice, not to be too arbitrary about normal weight standards but to give plenty of latitude to different types of individuals. There is plenty of obesity beyond such limits. The therapeutic results of weight reduction fully justify the effort. It is really essential to head up a sane, scientific movement in relation to obesity in a responsible organization or group within the profession in order to disseminate sound information in reference to the importance of weight control, complete nutrition and a properly balanced diet.

It is suggested that the gastro-enterological specialty accept the challenge and assume the leadership in an unsensational but persistent campaign for the popularization of weight control in connection with periodic health examinations or any form of personal preventive or curative medicine in private practice.

THROMBO-ULCERATIVE COLITIS

CHRONIC ulcerative colitis (colitis gravis) is now widely believed to be an infectious disease of the large intestine. A clearer understanding of the condition specifically designated as chronic ulcerative colitis and the realization that there are many ulcerative inflammatory processes of the colon which in the present state of knowledge cannot reasonably be included under this designation have, however, focused the attention of more and more students of this disease on the hypothesis that it is of streptococcal etiology.

A few workers still hold that the condition may be the end stage of an infection by organisms of what used to be called the colon-dysentery group, and which now would include Escherichia coli, Shigella dysenteriae, and Shigella paradysenteriae. Their belief is based on the finding of these microörganisms in a few cases of ulcerative colonic disease, a slightly elevated concentration of antibodies of these organisms in the blood of a few patients and the therapeutic response of some of the patients to administration of antidysentery serum. In study of a large number of patients who have this disease, and in study of another group of patients who have other types of intestinal disorder, including cancer of the colon, infectious granuloma, amebiasis and irritable colon, as well as in study of normal individuals, a similar elevation of the concentration of antibodies of these organisms has been found. Because of these findings, and because men who have held to this belief have selected their cases from regions where the Bacillus dysenteriae is prevalent, this hypothesis of causation would hardly seem tenable.

Another hypothesis of etiology has as its basis the idea of infection by a variety of organisms. The thought has been that many kinds of bacteria, under special conditions, may initiate the pathologic process and may be responsible, in some instances, for its continuance. Among the organisms so incriminated have been Escherichia coli, pneumococci, staphylococci, and others. It has been suggested that the normal intestinal inhabitants assume virulence when bodily defense to infection becomes reduced. The same could be said about any infectious disease, but that would not necessarily permit incrimination of the bacteria present at the site of infection late in the course of the disease.

A third hypothesis of etiology has been concerned with deficiency of vitamins, minerals, and other substances. Studies of large numbers of cases would suggest that when deficiencies occur, they are not primary but occur more as complications of the disease.

Another hypothesis of causation of this disease has been concerned with changes in bodily metabolism, such as occur in diabetes, goiter and similar diseases. Experimental evidence for this is lacking.

Others have explained the condition as the result of a residual infection following infestation by amebas and other parasites. There is much to support the thought that when parasites occur in association with chronic ulcerative colitis, either two separate conditions are present, in which the parasites are causing only part of the symptoms, or they are only incidental intestinal inhabitants.

The most widespread view, and one which is supported by much experimental evidence, is that chronic ulcerative colitis is an infectious disease, caused by a specific microörganism or by a group of microörganisms. The group of microörganisms is of the streptococcal variety and much evidence is at hand to suggest that a diplostreptococcal form of characteristic biologic and morphologic properties is at least one of the main instigators of the disease. In the light of present-day knowledge such an organism must be considered the inciting factor in this disease. Whether or not the organism alone is responsible for the infection, or whether its association with a filtrable virus is important, has been a recent subject of discussion. Some have suggested that the toxin of this organism is alone capable of producing the disease. This thought has led to the search for a filtrable virus. So far, the fact that both the toxin and the organisms seem to play parts in the inception of the infection, again would establish the importance of the presence of the diplostreptococcus.

Men have learned to recognize many factors which predispose to or lay the ground work for the invasion of this organism or its toxins. Among these should be mentioned infections of the upper part of the respiratory tract, such as tonsillitis, bronchitis, and sinusitis; pneumonia; distant foci of infection, particularly teeth with periapical infection; other systemic infectious conditions with intestinal manifestations, including bacillary dysentery and irritable colon; metabolic disturbances including pregnancy; dietary deficiencies and local trauma. These and other conditions seem to render the intestine more vulnerable to the invading organism but many times none of these,

or any other predisposing factors, seems to be at hand, and primary overwhelming invasion by the streptococcus can be demonstrated.

That a disease of such clear-cut clinical symptoms and pathologic signs should call forth a discussion of etiology, and should labor under so indefinite a term as "chronic ulcerative colitis," is unfortunate. Men of large experience in the study of gastro-intestinal problems are thinking of a well-defined entity when they designate an intestinal disease as chronic ulcerative colitis. All admit that the term is sufficiently indefinite to allow the inclusion under it of numerous nondescript conditions, as well as other specific, ulcerative diseases. This is, perhaps, the reason for different opinions on etiology in the past.

Careful analysis of much of the voluminous literature which has accumulated on ulcerative colitis in the last decade demonstrates that there still exists the tendency to classify any kind of colonic ulceration under the designation, "chronic ulcerative colitis." With the accumulation of more exact information on the nature of this most distressing intestinal infection, it has become increasingly apparent that many of the conditions previously thought classifiable under the designation "chronic ulcerative colitis" must be eliminated if the term is to be retained. Those cases in which there are characteristic clinical, sigmoidoscopic, and roentgenologic data represent an entity which should not be confused with other conditions. The history presented by the patients is exactly that which one would expect, judging from the nature of the intestinal pathologic change that is present. There is a diffuse inflammatory process involving the wall of the bowel, and resulting in a characteristic proctoscopic picture and a typical roentgenologic deformity. The nature of the history which the patients will give will depend on the extent of the disease and on the amount of damage to the bowel that has occurred.

All these observations serve to emphasize the importance of a suitable name for the disease now known as "chronic ulcerative colitis." The pathology of the condition, as it is seen in the living and in the dead, has been adequately described. Its sigmoidoscopic picture is clear cut and the steps in its development have been carefully and repeatedly observed and recorded. Its inception seems to have the following sequence: attack of the bowel through the blood stream by a microörganism or its toxin, resulting in multiple thrombosis of capillaries in the wall of the bowel, followed by tiny hemorrhagic infarcts, dissolution of these infarcts, formation of minute abscesses, and the appearance of the disease from the mucosal side as a granular, bleeding surface. Only cases in which this is the pathologic picture should be given a name which represents what is now known as chronic ulcerative colitis.

But since this name readily allows the inclusion of other ulcerative conditions, a more suitable and more descriptive term should be found. To this end many names have been considered and cast aside. The fact that the streptococcus is found to play a part in the picture makes it desirable that this fact be taken into consideration in choosing such a name. However, when etiology is brought into a name, such a name may become cumbersome. A mere description of pathology should be adequate. The designation "thrombo-ulcerative colitis" would be descriptive, clear cut, and would tend to avoid falsely classifying other conditions with this disease.

J. Arnold Bargen.

THE REGULATION OF GASTRIC ACIDITY

THE acidity of gastric contents can conceivably be regulated by several methods, namely (a) neutralization and dilution by alkaline fluid of gastric origin, (b) neutralization and dilution by fluids of extra-gastric origin, including ingested food, and (c) regulation of the production of HCl by the stomach. The first of these methods is admittedly of very minor importance. The mucous secretion of the stomach has an alkalinity of only 0.04 N and is small in volume (1).

The second possibility was emphasized by Boldyreff (2) who originated the theory of the auto-regulation of gastric acidity by regurgitation of alkaline intestinal contents. Since pancreatic juice is the most important component of the intestinal secretion both in point of volume and degree of alkalinity, it would play a prominent role in this mechanism. That regurgitation does occur is generally conceded, but all investigators have not been satisfied that it constitutes a major factor in the regulation of acidity.

The third factor, regulation of acid formation by the stomach, was considered of prime importance by Rosemann (3), who maintained that the acidity of the gastric juice varied with the rate of secretion of the latter. This alteration of the acidity was accomplished by the parietal cell, which Rosemann believed was able to convert into HCl a variable proportion of the NaCl passing through it. This theory has suffered considerably under the attack of recent investigators, who have adduced evidence favoring the view that the secretion of the parietal cell is a pure solution of HCl of a constant concentration (approximately 170 MM. or clinical units) (4, 5, 6, 7). These authors maintain that the variations in the acidity of pure gastric juice are due to the dilution and neutralization which results when variable quantities of this acid solution are secreted and mixed with a relatively constant quantity of another fluid consisting of mucus, sodium chloride, and buffers. This alkaline fluid is of such small volume as to significantly effect the acidity of gastric juice only when the rate of production of acid is very small. Since the acidity of gastric juice as normally secreted is much higher (0.4-0.5%) than that of normal gastric contents (0.2%), the question arises as to how the latter is maintained at this figure, if regurgitation is not the major factor.
